There are at this moment at the very least 500,000 American citizens afflicted with tuberculosis of the pulmonary type. It would, indeed, be terrible to think that their average mental state should be such as Dr. Saxe describes. Yet, I ask, is it possible to give any other interpretation to Dr. Saxe's conclusions than the one cited? However, if anyone is not yet quite convinced to what conclusions Dr. Saxe's studies have led him, he himself will come to the rescue, for in the "Summary and Conclusions" of his article we can again read on page 265, a reiteration which reads as follows: "The fundamental factors in the psychical make-up of the typical consumptive are the loss of self-control, the rise of brute selfishness, the increase of susceptibility to suggestion, to emotion, and to nervous irritation, and the tendency to rapid nervous and psychical fatigue." I cannot understand how Dr. Saxe, in the face of these quotations from his article, can say, in the Medical Record of January 23, 1904, "Nowhere do I say that a greater tendency to crime has been noted among consumptives than among other individuals, nor that the *average* consumptive, as the result of the mental peculiarities of which I have spoken, exhibits a distorted ethical perception."

In my article in the Medical Record I quoted only the essentials from letters received appertaining to the subject under consideration; however, I can assure Dr. Saxe that his article had been read by nearly all the gentlemen before replying to my inquiries, and that they were fully familiar with the contents of his communication in the *New York Medical Journal*. Therefore, in his inference that the replies were only answers to my questions, he is seriously in error.

Dr. Saxe tries to make it appear that I selected him as the only living example of a physician furthering phthisiophobia; in this, however, he is mistaken. I know of others, but as I said in my article, thank God, they are rare; they exist and have existed. I advise Dr. Saxe, who is so fond of reading medical history, to look up the works of Montano and Morgagni. He will there learn that he had some very illustrious predecessors who, by their writings, fostered phthisiophobia and made the lot of the consumptive a hard one. Montano, who lived in the latter part of the sixteenth century, stated in his works that one could contract pulmonary tuberculosis by simply walking with naked feet over the expectoration of a patient. The great anatomist, Morgagni (1682-1771), absolutely refused to perform autopsies on individuals who had died of pulmonary consumption, because of an exaggerated fear of the contagiousness of the disease.

That there are modern medical writers who have the same tendency to burden the lives of the consumptives and their families by their writings and rulings, Dr. Saxe knows as well as I do. Only recently some medical papers announced that the complete isolation of all tuberculous patients in the city of Sydney, Australia, had been contemplated upon the advice of the medical council.

Concerning the results of such articles as Dr. Saxe's when, as it unfortunately frequently happens, they are reproduced in the lay press, let me give the following incident: Among the queries asked in an open letter on "The Mental Status of Phthisis," which appeared in the *Journal of the American Medical Association*, of August 29, 1903, we read the following: "Are persons, afflicted with pulmonary tuberculosis, more easily turned against their dearest friends by designing people than when in a normal state?" Let Dr. Saxe remember that this letter appeared after extracts of his article had made the round in medical and lay papers.

In closing, I would wish to give Dr. Saxe the advice never to draw general conclusions from one or even a dozen reported cases of pulmonary tuberculosis, but rather to study the cases himself, and after having seen a goodly number and observed them for a long time, then only, and not before, should he publish his conclusions.

There is, perhaps, no man in this country, nor abroad, who has seen more consumptives, observed them longer, and watched them more closely, than Dr. Edward L. Trudeau, the founder of the first sanatorium for consumptives in this country. Let me recall to Dr. Saxe Dr. Trudeau's expression of opinion of the moral, mental, and psychical state of the average consumptive: "I have never noticed any greater tendency to immorality or crime among consumptives than is to be found in the average of the human race, as far as it has come under my observation. On the contrary, I have seen all the finer traits of human nature developed to the fullest extent by the burdens which chronic and fatal illness, often slow in its progress, adds to the sum total of what men and women usually have to endure in life. I have seen certainly more patience, courage, self-denial, and unselfish devotion to others in consumptives than I have noticed in the majority of healthy human beings."

Diabetes and Obscure Physiology.—C. Ramus believes that current teaching in regard to diabetes may be expressed in the following propositions: (1) That in normal blood dextrose undergoes chemical modification before absorption by the tissues. (2) That in normal blood alcohol develops from disintegration of dextrose. (3) That alcohol is present in minute quantities in the urine of total abstainers. (4) That in chemically pure solutions of dextrose and levulose treated with pancreatin, sugar is lost and alcohol (and carbonic acid?) developed, the change being more marked in the case of levulose. (5) That the agent responsible for the chemical reaction is an enzyme normally present in blood. (6) That this enzyme has its origin in the pancreas alone, for when that organ is removed dextrose remains unchanged. (7) That interference with or disturbance of this function of the pancreas initiates a group of phenomena known clinically as diabetes mellitus. From these premises he argues to the conclusion that alcohol is a valuable remedy in diabetes. Reasonable amounts of it will relieve the pancreas, liver, and kidneys for the time being by furnishing prepared nourishment and force to the starving tissues. Diabetic phenomena are an expression of an abnormal condition wherein the (hypothetical) alcoholic function of the pancreas is disturbed.

Some of the Physical Properties and Medical Uses of Radium Salts; with Report of Forty-two Cases Treated by Pure Radium Bromide.—Francis H. Williams states that radium has five properties that especially deserve notice, which obtain constantly without appreciable loss in weight: (1) It maintains a temperature above its surroundings under thermal insulation; a temperature of 1.5° C. has been observed. (2) It is luminescent. (3) It is a spontaneous source of electricity. (4) It gives out three kinds of rays, named by Rutherford, alpha, beta, and gamma. (5) It produces in surrounding objects what Mme. Curie has called "induced radioactivity," what Rutherford has termed "excited radioactivity," and Soddy now designates as "imparted radioactivity." With our present knowledge of the subject, this latter word seems the most appropriate. This imparted radioactivity is caused by what Rutherford has named "emanation." The emanation, which is thought to be a gas, imparts radioactivity to objects that have been in the neighborhood of radium salts for a sufficient period: that is to say, these objects, even after removal from the radium, give out rays for a certain length of time. On account of their inability to show sufficient differentiation between the tissues, the rays from radium, unlike the *x*-rays, cannot be used for diagnosis or prognosis, either by means of radiographs or of the fluorescent screen. Therefore for these purposes they cannot replace the *x*-rays. The use of radium salts for thera-

peutic purposes needs much the same kind of experience as is required for the successful therapeutic use of the *x*-rays. Already a number of cases of injury to persons working with radium have been reported. Radium should be kept in a metal box or capsule with a thin mica front or other suitable covering, so that the radiations may be cut off in all directions except that in which the practitioner desires the rays to proceed. To such a capsule the writer has attached a long, flexible handle, in order to hold the radium at a distance when applying it. This handle is a protection to the physician. When not in use, the capsule should be placed in a thick lead box or tube, so that the radiations may be absorbed. It should be remembered that an over-exposure may cause a burn, which may not become evident for some time. It should also be remembered that exposures differ for different diseases, even superficial ones. Consequently experience is necessary to judge of the proper length of exposure and of its frequency. In certain cases exposures must be longer and in other cases shorter, and the frequency of exposures must vary. In conclusion the writer says that his experience thus far teaches him that there is much similarity between the action of the radiations from radium and the *x*-rays; that if the results obtained by radium prove permanent, this new therapeutic agent will be largely used instead of the *x*-rays, but that the two will supplement each other. (1) Certain diseases promise to yield more readily to treatment by radium and others to the *x*-rays. (2) A disease that has attacked different parts of the body of a given patient may be better treated in certain regions by radium and in others by the *x*-rays. (3) It is quite possible that in some cases the two remedies used together on the same area and at the same sitting may accomplish better results than either alone.

Two Advantageous Procedures in Anæsthesia Work.—Victor C. Pedersen speaks of the first procedure as a new sequence in which the series is nitrous oxide, then nitrous oxide and ether combined, and finally ether alone. The purposes of the technique are to avoid any gas cyanosis, to induce ether narcosis very slowly without exciting any reflexes, such as coughing, and finally to obtain a full degree of ether narcosis with the utmost safety and convenience to the patient. There is, too, a great economy of gas. The writer prefers the Bennett apparatus. The gas-bag is filled to its half capacity for the average patient. With the valves of the gas-chamber open, the patient is requested to breathe. As soon as he understands what is required of him and the face-piece is seen to fit air-tight, the gas is turned on. After from two to four full respirations with the expiration-valve of the gas-chamber open, this is closed so that "rebreathing" is initiated. The patient now takes from two to four respirations in this manner. When he is generally sufficiently under gas—narcosis for the next step. This consists in very slowly turning on the ether—so deliberately that it takes from four to eight minutes to pass from "air" to full "ether." The ether in the ether-chamber is judiciously replenished, and if necessary likewise increased. If there is any delay in the appearance of the normal ether respiration, the nitrous oxide ether combination is continued until it develops. When all the symptoms of complete ether—anæsthesia are present, the gas-chamber and bag are removed, and the ether bag is attached to the ether-chamber, and the patient is ready for operation. The second procedure has reference to the position of the patient for operations upon the kidney, and is described by the writer as follows: After the patient is narcotized in the dorsal position, he is transferred to the operating table, turned up on his side, and the Edebohls' bag is placed in position. The shoulders are then raised from the table and rested upon a sand-bag reaching from shoulder to shoulder, oval in cross-section, about four inches in its longest diameter and reasonably soft. This brings the pressure of the chest upon the shoulders and upper sternum, and not as heretofore, upon the base of the neck. When the shoulders are thus elevated free of the table the heat may be moved in any direction whatever, and the jaw of the patient is absolutely under the control of the anæsthesist. The writer places other sand-bags under the Edebohls' bag, thus securing a proper flexion and torsion of the chest upon the abdomen. The writer adds that he cannot lay too much stress on the importance of securing freedom of the head and neck as a most important aid to the narcotizer in giving any anæsthetic as uneventfully as the idiocyncrasy of his patient will permit.

New York Medical Journal, February 6, 1904.

The Sanitary Needs of Panama.—M. L. Maduro, who has practised in Panama, discusses the sanitary conditions of the city and declares the following things necessary to make the city healthful: (1) The deduction of all the rookeries inhabited by the very poor and the transfer of the latter to decent dwellings. (2) The organization of an efficient street-cleaning department. (3) The opening up of all the narrow streets to the sunlight, paving of streets and filling up of all vaults and cisterns. (4) The establishment of a board of health with the usual function. (5) The enforcement of strict quarantine regulations.

Infantile Bronchitis.—E. M. Sill discusses the anatomical peculiarities of the infantile lung and describes the clinical course of the disease named. It is of great importance to stimulate cough so as to clear the air tubes. Otherwise the patient may drown in his own secretions. For this purpose nothing is better than syrup of ipecac and citrate of potash in the first stage, and in the second, ammonium muriate and terebene. The objects to be accomplished are to rid the lungs of the excessive secretions, prevent the bronchial tubes from being filled up by more secretion, and support the heart and respiration until the crisis is over. When the lungs are rapidly being filled with secretion, nothing is better, in a strong child, than an emetic; ipecac may be used in the form of the powder, five to ten grains, or a teaspoonful of the syrup of ipecac. Aconite may be used to control a strong and full pulse and digitalis to stimulate it if necessary.

American Medicine, February 6, 1904.

Some Observations on the Occurrence of Nephritis in Infancy.—Charles C. Biedert states that infantile nephritis may occur as a primary or as a secondary affection. The primary form is very rare in infants. The secondary form usually develops at the height of the febrile process, and its severity is generally proportionate to the intensity of the infection. The general symptoms are often not marked, so that unless the urine is examined the condition is overlooked. In Holt's analysis of four hundred and twenty-six cases of bronchopneumonia, occurring in children under three, there were only three cases of nephritis, and in all of them it was of the acute exudative variety. More attention has been paid to the occurrence of nephritis following gastroenteric diseases than of any other. Morse, in a series of seventy cases, found evidence of renal involvement in 15 per cent. The writer, in conclusion, emphasizes the following points: (1) The importance of examining the urine in all acute diseases of infancy, and especially in the bronchopneumonias. (2) The importance of marked anæmia as the most pronounced symptom of kidney involvement. (3) Œdema may or may not be present, but when it is present it constitutes a valuable sign, but there may be grave kidney involvement without œdema. (4) There is almost always a diminished secretion of urine, the mother almost always noting that the baby wets fewer napkins. (5) There are almost always grave nervous phenomena and convulsions, which in some cases are probably uræmic.

Myxœdema Complicated with Diabetes Mellitus Occurring in Two Children; Effect of Thyroid Extract upon Both Diseases.—Alfred Gordon presents in this paper two cases of myxœdema with genuine diabetes mellitus in brothers who are the offspring of neuropathic parents with degenerative tendencies. Thyroid extract in both patients showed a very favorable influence upon both morbid conditions, and even earlier on the diabetes than on the myxœdema. The cases present several unusual features: (1) The coincidence of myxœdema and a genuine diabetes mellitus (not a simple glycosuria); (2) the occurrence of diabetes in early childhood; (3) the occurrence of both diseases in two brothers, showing a degenerative hereditary tendency; the latter is corroborated by the interesting family history; (4) the remarkable effect of the thyroid extract upon the diabetes, explaining with a great degree of certainty the rôle of the thyroid gland in the as yet unknown pathologic metabolism, which is manifested in a group of symptoms called diabetes mellitus. So far none of the theories advanced suffices to explain all the phenomena of the malady. It seems highly probable that independently of the digestive functions there is a special internal secretion of the pancreas which is at fault. It is a well-established fact that diabetes has been seen in diseases of the thyroid gland. Whether the thyroid disorder is the direct cause of the diabetes or acts indirectly through the pancreas, similar to the effect of the adrenals, the writer believes it is difficult to say. Diabetes, especially in children, usually presents an unfavorable prognosis. The cases here reported, on the contrary, presented a very favorable course and were satisfactorily influenced by thyroid treatment. These patients were aged three and four and a half years, respectively. The writer asks if the history of these cases is not an indication that a diabetes dependent upon a deficient thyroid function is a form far less grave than the form of the disease which is caused directly by de-

struction of or a pathologic condition of the islands of Langerhans?

Morton's Painful Disease of the Toes.—Walter G. Stern believes that this disease is the property and privilege of the comparatively well-to-do and is quite frequent among them; while the poor, who do not usually indulge in narrow, thin-soled, uncomfortable shoes, are rarely afflicted. The writer says that the view which he believes to be universally admitted to-day, takes the stand that Morton's disease is purely a static condition of the transverse arch of the foot, quite analogous to flat-foot. The anatomic foundation for this disease is laid when the foot is subjected to a severe trauma, or when it is weakened from long illness, or when it is overburdened by rapid increase in body-weight, so that the ligaments cannot hold the anterior arch in its normal condition, but permit the heads of the bones to press against the sole. This condition need not always be painful. This disease is a clinical surgical entity. Careful questioning will nearly always elicit the history of a severe trauma shortly before the pain first came on. The symptoms are a sudden feeling of uncomfortableness in the ball of the foot, often accompanied by a snapping in the afflicted toe; then an intense, agonizing, burning, unendurable pain radiating from the fourth metatarsal head (it may be any other) through the thickness of the foot up upon the dorsum, followed often by faintness, cold sweats, and a total incapacity for the time of thinking of anything else. A pathognomonic feature of this disease is the insane desire to remove the shoe regardless of the surroundings. Examination rarely reveals any stigma of nervous degeneration. The feet are generally large and especially broad across the ball of the toes. The affliction may be hereditary Of all cases, 75 per cent. are among women, usually of middle life, but some cases have occurred in childhood. As to treatment, mechanical aid is used to reform the flattened anterior arch much as we do to correct the arch of flat-foot. The writer proposes in his future cases to fasten pads of soft rubber to a flat German silver insole to give a much-needed elasticity not found in Whitman's plates. Intractable cases can often be relieved only by means of incision.

The Lancet, January 23, 1904.

Facial Palsy as a Family Disease.—J. A. Arkwright records the history of five cases occurring in the same family, and he inclines to the truth of the view held by Neumann that although a cold draught may act as the exciting cause of a facial palsy, a very strong predisposition thereto may be inborn.

An Early Symptom of Acholia.—H. J. Van Praagh mentions as an early symptom of acholia a coldness and dryness of the extremities. In the case of a girl of between two and three years, he was able to ward off the attacks with their usual anorexia, wasting porridge-like gray stools composed chiefly of fatty matter, etc., by having the patient sleep between blankets with a hot-water bottle and having her legs well covered during the day. He suggests that changes in atmospheric conditions may act as exciting causes of acholia in children predisposed to temporary loss of hepatic function.

Two Cases of Osteitis Deformans in One Family.—The two patients of W. J. Kilner were brother and sister, both past middle life. The woman's case was a typical one in all its features, while the man's lacked one important symptom of the disease, namely, the enlargement of the cranial bones. The author believes this to be the first instance on record in which two members of the same family have been afflicted with this malady. The disease began in both insidiously and almost simultaneously. One patient had always lived well, while the other had been subjected to great privations, and the author states that neither mode of living nor climatic conditions have any influence in causing the disease. He is inclined to regard it as primarily due to some systemic dyscrasia, that is, it is a general disease with secondary bone changes.

A Case of Acute Traumatic Cholecystitis.—The history of the case reported by F. J. Smith and C. W. Mansell Moullin is that of a man aged fifty-nine years who fell on some ice, striking his right side. Some six days later he had pains in the side and abdominal swelling. Examination two days later showed marked tenderness over the gall-bladder. The temperature rose to between 99° and 101°. Abdominal exploration led to no definite diagnosis and a median incision was finally made. One small omental hemorrhage was discovered. The patient gradually sank and died thirty-six hours later. The autopsy revealed as the only pathological condition, the state of the gall-bladder. This was seen to be externally inflamed, of a brown color, and with patches of lymph scattered over it. It was moderately distended and the connective tissue round it was dark in color and evidently not healthy. On cutting it open the distension was found to be due to what was very evidently blood, though considerably altered by decomposition. The lining membrane was more or less necrotic and soaked in blood and discolored with the soaking. There were no gallstones and no appearance whatever even faintly suggestive of a growth.

The Lancet, January 30, 1904.

Notes on the Treatment of Tuberculous Meningitis.—J. Gilroy gives the notes of a case in which liquid extract of ergot, five minims being given with bromide and iodide of potash every two hours. The patient was a girl of four years. The scalp was shaved and ice at first applied; later on iodoform ointment was used. The diagnosis of tuberculous disease was strongly probable from the family history. Good results also followed in a case of Bell's mania occurring in a woman of fifty years.

The Value of Ichthyol in Tuberculous Glands.—W. Overend advocates the use of ichthyol. He notes, however, some difficulties in its internal administration. Even in solution with a large quantity of glycerin and peppermint the remedy is particularly nauseous; in the liquid form ichthyol can hardly be taken. Made into a jelly with gelatin it is not much better, and children, as a rule, will neither take pills nor capsules, but they will readily take tablets when made thin and rather smaller than the ordinary size. Tablets of ferrichthyol, each containing one and a half grains of ichthyol combined with iron, probably carbonate or reduced iron, may be given three times a day after meals. Good results with these combinations of the remedy are reported in several cases.

Note on the Probable Mode of Infection by the So-called Filaria Perstans, and on the Probability that This Organism Really Belongs to the Genus Tylenchus (Bastian).—This question is discussed by H. Charlton Bastian, who alludes to the reports of Christy that the distribution of the filaria perstans in East Equatorial Africa corresponds almost exactly with the area of "distribution of banana cultivation and clothed people." It has been shown that the parasites in question are to be found in banana roots, and Bastian calls attention to the fact that the nematoids which were found on the nodosities of certain cucumber plants in England belonged to the genus tylenchus, and he is inclined to believe that the cucumber and banana parasites are identical. The filaria perstans is probably taken in with the food, bores its way through the intestinal canal, and settles in the mesentery and adjacent parts there undergoing development. Thence the worm gets into the lymph stream and finally into the blood.

The Efficient Treatment of Cardiac Failure.—A. Morrison divides cardiac failure into acute and chronic, and makes an earnest plea for the abandonment of the pessimistic views so current in regard to cardiac therapeutics. Four factors are concerned in cardiac action: neural, muscular, hæmic and mechanical, and our selection of remedies must be based upon a realization of this fact and a proper selection of remedies in accordance therewith. The heart of angina pectoris is a flaccid diastolic heart; hence we should use rapidly acting remedies such as amyl nitrite and morphine and atropine, alone or combined with volatile anæsthetics. In muscular failure we should give digitalis or its synergists, combining them in severe cases with mercurials or powerful vasomotor agents such as the nitrites. In very bad cases venesection-drainage of anasarcous limbs, paracentesis of chest or abdomen are all indicated. In hæmic cases the trouble may be due to quality (opium) quantity (venesection) or distribution of the blood. Mechanical factors concern especially valvular action. Under this head the author discusses the usual indications and contraindications of the digitalis group.

British Medical Journal, January 23, 1904.

Etiology of Carcinoma.—Keith W. Monsarrat presents the following summary of researches: (1) From a considerable proportion (58.3 per cent) of specimens of carcinoma mammæ an organism presenting characteristic features was isolated. (2) This organism presents a life history in which two cycles were traced—the one a vegetative budding cycle, the other a sporulating cycle. (3) The organism when injected into animals is capable of infecting and inhabiting endothelial and epithelial cells. (4) The organism initiates in endothelium and epithelium a process of proliferation, as a result of which masses of new-formed tissue are built up which consist of a parenchyma and a stroma, and grow and extend actively from their centers of origin. (5) This new cell mass formation may be associated with growth of similar character in neighboring glands, and some evidence was also provided that visceral metastasis occurs. (6) Intracellular bodies are demonstrable in carcinomata mammæ, which present the same features as the intracellular parasites of the experimentally produced nodules. (7)

The evidence derived from these researches points to the conclusion that the organism described is an etiological factor in the morbid process known as carcinoma mammæ.

The Leishman-Donovan Body and Tropical Splenomegaly.—Patrick Manson and George C. Low think that it is possible that certain cases of tropical disease in which enlargement of the spleen is a prominent feature and which hitherto have not been adequately recognized or explained are due to the trypanosoma. They describe a case in which examination of the blood obtained by splenic puncture revealed Leishman-Donovan bodies in great profusion. Although these parasites were often seen superposed on or underlying a red corpuscle, the writers have not seen anything that would lead them to believe that these parasites were inside the corpuscle. Examinations were made in ordinary wet blood preparations, in hanging-drop preparations and in dried and stained films. The stains employed were the Leishman-Romanowsky carbol-fuchsin and carbol-thionin. The first stain gave by far the best results. It is evident, according to the writers, that the parasite must get out of the body somehow and that the blood is the most probable channel. On tapping the liver of this patient numerous single or double parasites, but no zoogloea masses were obtained. This seemed to point to the biliary ducts as the channel through which the parasites escaped. But repeated examinations of the fæces were negative. Centrifuged urine also yielded no parasites. The writers append to the history of the case a temperature chart and the results of three blood counts.

Human Trypanosomiasis on the Congo.—J. Everett Dutton, J. L. Todd, and Cuthbert Christy declare that the examination of trypanosomes seen in stained specimens of blood from cases of trypanosomiasis, from cases of sleeping sickness (typical or doubtful), in the specimens of cerebrospinal fluid of the latter cases, and in the blood of experimental animals, infected with either of three above-mentioned fluids, has led us to the following conclusions: (1) The trypanosomes seen in the blood of man, whether symptoms of sleeping sickness were present or not, have always been the same. The number of cases in which trypanosomes from the spinal fluid have been examined is at present too small to permit of a definite description of morphologic characteristics. The writers have seen forms in the cerebrospinal fluid similar to those described by Bruce and Castellani, and also longer forms similar to those seen in the finger blood of the same cases. (2) None of the human trypanosomes seen, whatever their source, have presented any morphologic appearance incompatible with trypanosoma gambiense. (3) The parasites seen in rats inoculated with the cerebrospinal fluid of cases admitted to the hospital for sleeping sickness are the same as those seen in rats inoculated with the blood of cases of either sleeping sickness or simple trypanosomiasis. (4) The organisms seen in the blood of rats inoculated with trypansomes from any of the three indicated sources have up to the present shown no differences from those observed in animals infected with trypanosoma gambiense.

Deutsche medizinische Wochenschrift, January 21, 1904.

The Effect of Mountain and Sea Air on Man.—Loewy says that although these two types of climate have much in common, yet they also require a certain amount of discrimination in their application as therapeutic measures. Both are useful when stimulation is required, but are to be used with caution when over-action already exists. The chief element of difference appears to be the increased production of red blood cells occurring in mountain air, but further studies are necessary to determine whether a similar effect may also be attributed to sea air. Mountain air owes its stimulating properties less to its attenuation than to the effect of the bright sunlight, the air currents and the temperature, while perhaps its electrical qualities also play a certain part. In company with several others the author studied his own metabolism while in the mountains and at the seashore, and found that in the latter region the metabolic activity was usually stimulated to various degrees, though some individuals were not affected. There is also a difference of susceptibility for sea or mountain air, some persons being stimulated by the one and not by the other.

A Case of Sepsis Due to the Staphylococcus.—Niedner reports this case, which is interesting from the closeness with which it resembled typhoid fever. The patient was a man of thirty-eight years, who fell from a ladder, and suffered excoriations and contusions of the gluteal region and elbow. He continued at work, but two weeks later was obliged to consult a physician for pain in the injured arm and thigh. Cupping was ordered, but instead of this the attendant massaged the parts, and in consequence the patient's condition rapidly became worse, so that ten days later the diagnosis of typhoid fever was made. The clinical course closely corresponded with that of this condition, though the bacteriological evidence was negative until a blood culture showing staphylococci was obtained. The patient finally died after a suppurative parotitis had developed. The autopsy showed large abscesses in the buttock and elbow, and the usual secondary lesions of sepsis, which were particularly marked in the intestine. The staphylococcus was found in pure culture. Evidently the fall had produced muscular extravasation, which became infected through the abrasions, and the massage caused dissemination of the organisms.

Berliner klinische Wochenschrift, January 18, 1904.

Experimental Observations on the Internal Administration of a Tuberculous Antitoxin.—Figari prepared a convenient and stable form of antitoxin by drying the blood of immunized calves and horses in the water bath, at a temperature not exceeding 55° C., and then finishing the process of desiccation with sulphuric acid *in vacuo*. The dried clot so obtained was powdered and given to guinea-pigs in doses of 3 gm. daily. After twenty-five days of treatment their serum showed on agglutination at 1 to 5 in twenty-four hours. After fifty-four days the reaction was produced at a concentration of 1 to 12 in twenty-four hours. After eighty-five days it agglutinated at 1 to 25 in twenty-four hours and at 1 to 10 in six hours. After eighty-five days the animals were given a fatal dose of tuberculin. Half of them lived for thirty-six hours, while control animals died in twelve to sixteen hours. The other half survived the injection. Marked improvement in the general condition and in the agglutinative power of the blood was produced in a consumptive patient who received 4 gm. daily of the powder for eighty days.

The Nature of Gout and Its Treatment.—Falkenstein, who is himself a sufferer from the disease, says that practical and theoretical considerations point to the stomach as the seat of the lesion originating the gouty diathesis, and that a deficiency in HCl formation underlies the whole trouble. The healthy individual through his active HCl secretion is able to handle even an excess of food and oxidize it to urea while the arthritic patient suffers from fermentation, deficient oxidation, and the formation of uric acid either through deficient splitting up of the molecules or through synthesis from the purin bodies. His plan of treatment is to give hydrochloric acid continuously in large amounts, and he has found, both with himself and patients, that this confers immunity from attacks. Ten to fifteen drops of concentrated hydrochloric acid are added to one or two large glasses of carbonated water at each meal, the total daily amount ranging from forty to sixty drops. All the concomitant symptoms, such as the headache, thirst, bad taste in the mouth, the decay of the teeth, the chronic bronchitis, insomnia, irritability, eczema, etc., subside under this treatment. Of other drugs the author warns especially against the use of alkalies, either during or between the attacks, and he also condemns colchicum, which impedes the elimination of the accumulated urates, so that though it gives temporary relief during one or two attacks, the seizures come on more frequently and with greater violence. The value of the alkalies lies solely in their power of combining with the organic acids of the stomach and in promoting diuresis. This object is just as well attained by the use of a carbonated water.

French and Italian Journals.

Contributions to the Study of Pneumococcic Peritonitis of Children.—Francisco Gaite says that clinical experience and reported cases show that (1) Pneumococcic peritonitis is more frequent in childhood. (2) The female sex is more predisposed to the disease. (3) There are various pathogenic varieties of the peritonitis. It can originate from the spread of pneumococci from the intestines, from the pleura, from the female genital tract and probably also from the blood. (4) In case of early intervention the prognosis for a localized infection is good. In case of diffused infection it is doubtful.—*Rivista di Clinica Pediatrica*, December, 1903.

Diaphragmatic Enterostomy.—A. Cossett describes a new operation for gastrectomy. The diaphragmatic opening is carried to the cardiac end of the stomach, allowing an easy suturing of the œsophagus to the intestine (in the cadaver). The operation is in two movements: First, abdominal, freeing the pylorus and the gastric attachments, making a gastroenterostomy; second, thoracic—the cardiac end is freed, the stomach is removed, and the operation ends in an anastomosis of the œsophagus and the lower end of the jejunum. Experimentally, three operations may be performed through the diaphragm: (1) Lateral anastomosis of the œsophagus and intestine, that

is, a trans-diaphragmatic enterostomy; (2) Anastomosis by grafting the œsophagus on the greater curvature; (3) total gastrectomy by the abdomino-thoracic route with an œsophago-enterostomy.—*Revue de Chirurgie*, December 1, 1903.

Sterility in the Female.—J. A. Doléres says that the prefers a bilateral cuneiform incision of the cervix. He makes a double angular incision about a centimeter and a half long on both sides of the cervix. The apex is cut deep and the base superficial; they are V-shaped openings toward the extremity of the cervix. This can be done without pain, and chloroform is not necessary. For hæmostasis a thermocautery is used, and ten days of iodoform gauze accomplishes the cure. The os remains open, and it is impossible for the lips to come in contact, and the procedure has given some brilliant successes. In default of this operation the author has recourse to the plastic operation of Simon—not Schroeder's—that is, a conical excision of the free border of the cervix, which leaves a free opening well lined within with mucous membrane and ciliated epithelium. This operation is contraindicated in the treatment of chronic cervicitis. The author prefers the double lateral cuneiform incision, or the plastic amputation of Simon, because he considers them superior to all other methods in the cure of sterility.—*La Gynécologie*, December, 1903.

The Association of Scarlet Fever and Typhoid Fever.—There is a special interest in the cases reported by V. le Goïe, because of the combination of these diseases rather than a simple association. The nature of the eruption was a little dubious at first and the cases were left under observation before isolating them, which is not done with the cases showing the usual scarlatina rash. The typhoid fever seems to have lessened the eruption in the beginning, but without destroying all its characteristics. It is difficult to determine the part played by each disease. Kelsch says that according to Taupin, typhoid fever lessens to an indefinite degree the characteristics of all the eruptive fevers with which it is in combination. The prodromæs are usually lacking, and the eruptions are pale and not abundant; but this is not always the case, for in some cases of typhoido-scarlatina the scarlatina has dominated the typhoidal process. The association of scarlet and typhoid fevers is usually admitted by the authors who have studied the question carefully.—*Revue de Médecine*, January, 1904.

A Case of Epilepsy Dependent on Unilateral Ocular Atrophy.—Ernesto Zoccali thinks that the functional and anatomical asymmetry which was present in the nervous system of the patient, resulting from the ocular atrophy, is the most important characteristic of epilepsy. The instability of the cerebral cells is also an important factor in epilepsy. It is well known that lesions of the visual apparatus provoke epilepsy very readily. Similar cases have been reported, notably the case of Colucci. All these facts combine to prove positively that the epilepsy in the case under consideration came from the atrophy of the eye. The reason that medical literature appears to take very little cognizance of similar cases is probably because the practising physician does not report all the cases which he observes and because his mind is taken up with the commoner causes of epilepsy as the neuropathic hereditary taint, intoxication, or any other commonly recognized cause, and he is too busy to look further for hidden things and his mind too preoccupied for him to notice this unsuspected cause. The author thinks that in this case the epilepsy unquestionably resulted from the atrophy or ablation of the eye.—*Giornale Internazionale delle Scienze Mediche*, January 15, 1904.

Fibromata of the Spermatic Cord.—A. Bruneau and H. Coudode Satriano hold that the diagnosis of this condition is very difficult. It is necessary to differentiate an affection of the cord from one of the neighboring structures, such as testicular tumor, hæmatocele, and hernia, and the nature of the tumor, whether benign or malignant, must be determined. When the fibroma has an inguinal origin and the tumor protrudes from the inguinal canal it cannot be differentiated from hernia. Only in the late stages of development would one suspect a benign tumor of the cord. The differential diagnosis from other benign tumors is still more difficult. Cysts are recognized by fluctuation and by exploratory puncture. Lipoma has a softer consistency and is generally lobulated. Differentiation from fibromyoma requires a microscopical examination, but as the treatment and course are identical, the postoperative differential diagnosis is sufficient. The prognosis is good because these tumors are bening and do not recur after operation. The treatment is operation to relieve pain and the functional disturbances, and also on account of possible later change to a malignant growth. Castration is necessary because the tumor is so intimately connected with the cord that it is impossible to separate it.—*Revue de Chirurgie*, January 10, 1904.

Hereditary Syphilis in the Second Generation.—Vincenzo Chirivino writes interestingly of two supposed hereditary syphilitics, grand children of syphilitics. The proofs offered are fairly conclusive, but these are not entirely unquestionable and there are a few doubtful points. The positive points, however, easily outweigh the doubtful ones, which are very few considering the difficulty of getting a full present and past history for three consecutive generations. The author reports two cases with almost unquestionably conclusive history of hereditary syphilis in the second generation, both showing characteristic syphilitic lesions. One case did not develop serious syphilitic lesions until she was five years old; but she had a papular eruption characteristic of syphilis in her mouth when only a month old. Neither of her parents showed any syphilitic signs, and the taint must have been dormant in them to reappear in the grandchild. Her father has a history clear of syphilitic taint, while her mother was the daughter of a woman who died of malignant syphilis. This shows the infection coming through the mother, as would have been expected The other case, a boy, showed characteristic syphilitic lesions at birth. His parents were both hereditary syphilitics.—*Giornale Internazionale delle Scienze Mediche*, January 15, 1904.

Myomectomy of the Gravid Uterus.—R. Condamire thinks that myomectomy is especially indicated in the gravid uterus when the symptoms are extremely painful and persistent and when the situation of the fibroma would prevent a normal delivery. The risk of abortion should be avoided by operating at the earliest possible moment and removing the threatening tumor, at the same time avoiding complications in the confinement. The operation is indicated when the presence of a fibroma has caused one or more abortions already. Without consideration of pregnancy the operation is indicated in a woman under thirty-eight or forty years of age, who wants to preserve the child-bearing function. The author thinks that myomectomy, which is an especially conservative operation, has lost ground; while of late years the technique of hysterectomy has evidently been improved. Also the question of the greater gravity of this operation started by the advocates of myomectomy has recoiled against them, and the general opinion is that a hysterectomy for fibroma is less dangerous than an enucleation from the operative point of view and also from that of recurrence. He does not think there is any occasion to compare myomectomy and hysterectomy in reference to a gravid uterus. Myomectomy is indicated under certain conditions, and when these do not exist, total removal should be chosen for a fibromatous uterus.—*Lyon Médical*, January 17, 1904.

Meningeal Complications in Pneumonia.—Merklen states that in the bronchopneumonia of infants, without any meningeal symptoms, there are changes in the cerebrospinal fluid resulting from meningitis or œdema, resulting from vasomotor disturbances of toxic origin. He reports a case in a man aged twenty, who showed on the fifth day of a pneumonia, meningeal symptoms, such as Kernig's sign, strabismus, trismus, etc., which lasted with brief intermission to the eighteenth day. The lumbar puncture, done on the sixth and twelfth days, showed no leucocytes or bacteria in the spinal fluid. Albumin was found in considerable quantity on the first puncture and only a trace the second time. The chlorides were diminished on both occasions. In this case the symptoms cannot be called hysterical. The patient had never had any nervous disturbances, nor did he show any physical abnormality, besides which his cerebrospinal fluid was affected to a slight degree. The fluid clearly showed the absence of suppurative meningitis. A group of cases exists in which there are meningeal symptoms, while on autopsy or lumbar puncture no suppuration of the meninges is found. But sometimes the fluid shows only the faintest trace of leucocytes or chemical change (as albumin), and often post-mortem œdema or congestion of the meninges is demonstrated.—*La Tribune Médicale*, No. 3, 1904.

Rational Treatment of Osteomalacia.—Albert Robin and Maurice Binet think that in their three cases they observed disturbances of nutrition shown in the respiratory and general chemical changes and in the composition of the blood. The disturbances of the respiratory exchange showed an increased formation of carbonic acid, and deficient absorption of oxygen by the tissues, to accomplish the oxydization of the nitrogenous substances. During digestion the production of carbonic acid is not increased and if the consumption of oxygen is increased, it is not due to oxidization of the carbon but of the nitrogenous substances which is very much increased. The digestion of the carbons is much retarded and that of the albuminous substances requires the absorption of an abnormally large quantity of oxgyen. Among the general chemica

changes the metabolism of the nitrogen is diminished, the change in the tissues rich in phosphorous as the nervous system are diminished, and the excretion of lime is very much increased. The blood shows these changes; lowered density, decreased hæmoglobin, inorganic salts, chlorine, and alkinity. The following therapeutic indications are present; increase the oxydization of the nitrogenous substances; increase the hæmoglobin, all alkalinity, and mineral salts of the blood; regulate the excretion of lime and manganese; increase the earthy deposits in the bones; and increase the phosphoric changes —*Archives Latines de Médecine et de Biologie*, December 20, 1903.

The American Journal of the Medical Sciences, Jan., 1904.

Acute Suppurative Thyroiditis.—Henry Roth states that this is a very rare condition, and is usually secondary to some infectious disease. The writer reports a case in which this affection was primary. The enlarged gland was incised, and a few drops of pus escaped. The gland showed areas of necrosis. The patient died the next day. The infection in this case was due to the streptococcus, but the source of the infection could not be determined. The right lobe was more involved than the left. Symptoms of sepsis were preëminent. The local signs might have been those of an ordinary phlegmon, but the constitutional symptoms were too severe. The primary suppurative thyroiditis, early incision, and drainage are imperative.

The Differential Diagnosis of Typhoid Fever in Its Earliest Stages.—William Colby Rucker presents the following conclusions: (1) There is no single symptom in which alone an early diagnosis of typhoid fever can be made. It is only by careful consideration of the symptom-complex that a clinical diagnosis can be arrived at. (2) The most trustworthy, as well as the earliest, sign of typhoid fever is the presence in the circulating blood of the bacillus of Eberth. (3) The demonstration of the bacillus of eberth in the blood is not beyond any fairly well-equipped laboratory. (4) The bacillus of Eberth is found in the fæces later than in the blood, but with comparative ease. The presence of the bacillus typhosus in the fæces is of great value as a corroborative sign. (5) The presence of the bacillus typhosus in the rose spots is a trustworthy sign, but has no advantages over the examination of the blood from other localities. (6) The serum reaction of Widal is seldom demonstrable during the earliest stages of typhoid fever. It is of value only in the higher dilutions.

Desquamation of the Skin in Typhoid Fever.—David Riesman concludes that the following varieties of desquamation in typhoid fever may be distinguished: (1) That confined to the roseolar spots. In some cases each spot has a tiny vesicle upon its summit, which quickly passes into a thin, scale-like crust. (2) That appearing as a sequel of sudamina. This is confined to the areas that have been the seat of the sudaminal eruption. The desquamation is usually furfuraceous, but is sometimes scaly. It occurs upon the trunk and the proximal parts of the limbs, and is never seen upon the distal parts of the extremities or upon the face. It appears in the bathed and in the unbathed. (3) In some instances there is in typhoid fever an extensive, almost universal, desquamation, either furfuraceous or lamellar, which seems to be independent of sudamina, and in all probability is a trophic change analogous to the shedding of the hair. It affects the trunk and the roots of the limbs, and, rarely, also the face and the distal parts of the extremities. Usually, but not always, the extent and the intensity of the desquamation bears a relation to the severity of the fever.

The Cardiosplanchnic Phenomena.—Albert Abrams enumerates three factors which enter into consideration in the mechanism of blood supply to the splanchnic vessels. Contraction of the abdominal muscles, respiration, and the regulating vasomotor action of the splanchnic vessels. If the lower sternal region is first percussed in the standing, and then again in the recumbent posture, there will be noted a decided alteration in the percussion tone: in the former attitude it is resonant or even hyperresonant, in the latter it is dull or flat. This is the cardiosplanchnic phenomenon. Its explanation is simple: In the erect posture the blood leaves the right heart, and tends to accumulate in the splanchnic area, whereas recumbency opposes this influence of gravity. The writer then gives various examples to show the value of the phenomenon in diagnosis and treatment. In the case of enlarged liver or spleen, percussion in different attitudes, repeated inspirations, and abdominal compression, will solve the question as to how much of the enlargement is due to hyperæmia, and how much to tissue hyperplasia. A crucial test is the application of a vacuum cup to the abdomen. The elicitation of this phenomenon would prove valuable in the differential diagnosis of a dilated heart from a pericardial exudate; in the latter affection it would not be elicited. The more perfect the splanchnic vasomotor mechanism, the less pronounced the phenomenon. As regards this phenomenon in relation to treatment, the writer suggests by its use several possibilities in the direction of reëstablishing the circulation and in relieving the heart when it is overtaxed.

On the Visceral Manifestations of the Erythema Group of Skin Diseases.—William Osler adds here, to those already published, a new set of eleven cases. There have been seven deaths in the writer's series of cases—24.1 per cent. The members of the erythema group have not all the same etiology, and the individual members have a very diverse etiology. There is no constancy of action of the same poison in different persons, or even in the same person at different times. This is notoriously the case with the animal and vegetable substances causing urticaria. The chronic forms of urticaria probably illustrate a morbid and persistent sensitiveness of the cutaneous vessels to poisons of either intestinal or tissue origin. The importance of the local status is shown in that remarkable form of urticaria which comes on after exposure to cold. So long as the face is at a temperature above 60° F. the patient is all right, but exposure at 40° F. is followed at once by an outbreak of urticaria. A peculiarity that may be transmitted through several generations, as in angioneurotic œdema, must either be a morbid susceptibility of tissue or an inherited peculiarity of metabolism or both combined. Certain types of exudative erythema behave like an acute febrile disease. In many of the fevers there may be symptomatic erythemas. The visceral lesions are most diverse in situations and form, and vary considerably with the character of the eruptions. Certain skin lesions are associated secondarily with diseases of the internal organs. The writer then discusses the various complications, cerebral, respiratory, cardiac, gastrointestinal, renal; arthritis, and hemorrhages from the mucous membranes. One of the most constant features in this whole group is the recurring attacks of colic, sometimes with vomiting, sometimes with diarhœa, occasionally with the passage of blood. In fourteen of the cases there was acute nephritis. Acute endocarditis seems a rare complication. As to treatment, the very chronic cases with recurring colic for years may resist all measures. Courses of gray powder with careful dieting may be helpful. In certain severe cases nothing seems to arrest the progress. The chief danger is from the kidneys. Protracted rest in bed and a milk diet are the best measures in such cases.

A New Treatment for Wry-neck.—Leonard K. Hirshberg declares that the pathology of torticollis rests entirely upon negation and probability. The probability is in most cases that the kinesthetic centers for the sternocleidomastoid, splenius, trapezius, scaleni, and deep cervical muscles are the points of origin for the various spasms. Another way to express our ignorance is to say that torticollis is due to irritation of the nuclei of the neurons. There are many combinations of the various muscles which are possible in this affection. Individuals with neuropathic relatives or ancestry are more subject to torticollis than the average person. Congenital and rheumatic wry-neck are not included in this paper. The treatment of the first patient reported is given as follows: The faradic current was used for five minutes daily over a period of four months. The positive electrode was placed over the wrist and a roller (negative) electrode was applied over the healthy sternocleidomastoid and upper fasciculus of the trapezius on the unaffected side. Liquor potassii arsenitis was given in doses of two drops three times a day for four months. Almost from the beginning there was marked improvement. At the end of the treatment the patient's head was perfectly erect, and a scarcely perceptible stiffness of the muscles remained. The cosmetic result was excellent, and although the arsenic has been stopped for some time, there had been no return of the clonic spasms. In another case treatment consisted of a rigid diet and the application of the faradic current for five minutes daily to the muscles of the well side. Improvement was steady. In the third case the treatment was the same as in the first, and at the end of three weeks the patient discharged himself as cured. —*Maryland Medical Journal.*

Book Reviews.

MANUAL OF MEDICINE. By THOMAS KIRKPATRICK MONRO, M.A., M.D., Fellow of, and Examiner to, the Faculty of Physicians and Surgeons, Glasgow; Physician to Glasgow Royal Infirmary, and Professor of Medicine in St. Mungo's College; formerly Examiner in the University of Glasgow,: and Pathologist to the Victoria Infirmary. Philadelphia and New York: W. B. Saunders & Company. London: Bailliere, Tindall & Cox, 1903.

THE author intends that this work shall supply the place of larger textbooks in medicine for use by students and junior practitioners. The book includes excellent chapters on nervous diseases and skin diseases, as well as the subjects ordinarily present in works on general medicine. The descriptive matter has been well arranged and the space is apportioned with reference to the importance of the different diseases. The language is intentionally as simple as possible, and often the difficult and unusual terms have a bracketed definition attached. The teaching is sound, but the morbid anatomy is rather too short, although it includes the main practical points, and the directions for treatment are direct and reliable.

PRÉCIS D'ELECTRICITÉ MÉDICALE. Par E. CASTEX-Agrégé des Facultés de Médecine. Paris: F. R. de Rudeval, 1903.

BETWEEN the unbound covers there are 672 pages of rather closely printed matter giving the details of technique, electrophysiology, electrodiagnosis, electrotherapy, radiology, and phototherapy, illustrated by 208 figures in the text. These pages are well worth preserving in a stout cover. The weakest parts of the work are those dealing with treatment by the newer light and ray methods. So little is said, in fact, on therapy in this connection that the chapter gives the impression of having been added almost as an afterthought. The chapter on radiology, aside from radiotherapy, has been well worked up in over 100 pages. There is much that must appear quite new to one not keeping up almost daily familiarity with advances in the electrical world. This is becoming rapidly almost as true in medicine as it has been in commercial fields. Amongst other novelties, considerable space has been devoted to high-frequency currents.

THE PRINCIPLES OF THE OPEN-AIR TREATMENT OF PHTHISIS AND OF SANATORIUM CONSTRUCTION. By ARTHUR RANSOME, M.D., F.R.C.P., etc., Consulting Physician to the Manchester Hospital for Consumptives. London: Smith, Elder & Co., 1903.

THE literature of every phase of the tuberculosis question has become voluminous beyond all bounds. So much has been written especially about the "open-air" treatment that it has been in danger of falling into a mere empiricism. This danger the author has recognized, and his manual is an effort to place this plan of treatment on a thoroughly scientific basis. He therefore discusses the principles of sanatorium and open-air cure, certain bodily conditions resisting phthisis, principles of sanatorium construction, and home treatment by pure air. Several architectural plans of construction are appended.

Under the first head are considered air, sunlight, feeding, rest, exercise, bathing, blood-making, comfort, warmth, amusements, clothing, education, discipline, disposal of excreta, and medical staff and attendants. This list conveys an idea of the thoroughness with which the subject is treated. Detailed information is given regarding the construction of sanatoria. We know of no better work for consultation by the managers and physicians of such institutions. In this portion he has had the assistance of a practical architect, Mr. G. A. Bligh Livesay.

GENERAL PATHOLOGY. By Dr. ERNST ZIEGLER. Translated from the Tenth Revised German Edition. Edited by ALDRED SCOTT WARTHIN, Ph.D., M.D. New York: William Wood & Company, 1903.

WHEN a book reaches its tenth edition the task of the reviewer is light. A great many changes have been made. In this work we find that, in spite of the criticism directed against the author's views on inflammation and tumors, he has not made any change. Ziegler does not adopt the theory of the parasitic nature of the true tumors, in spite of Czerny's support to the contrary view. Especial attention has beeen given to the revision of the chapters on Vegetable and Animal Parasites. These chapters have also been enriched with very instructive illustrations. The chapters dealing with the Pathogenic Bacteria are complete and beautifully illustrated. Special mention should be made of the chapter dealing with Nematogenous pigments. Another interesting chapter, and one in which Ziegler demonstrates his proficiency, is the chapter in which he describes the parasitic fission-fungi, and the diseases caused by them For one desiring complete data regarding general pathology, and for advanced students in pathology, this book will serve as a valuable guide. Its bacteriological illustrations cannot be excelled. The arrangement of the book and its bibliography form a very valuable means of seeing at a glance all literature bearing on the various chapters under discussion. The paper is excellent. The print is clear, and the book is beautifully bound.

SYLLABUS OF LECTURES ON PHYSIOLOGY. By WILLIAM H. BIGLER, A.M., M.D., Professor of Physiology and Pediatrics, Hahnemann Medical College, Philadelphia, Pa. Second Edition. Revised and enlarged. Philadelphia: Boericke & Tafel, 1903.

THE appearance of the second edition of this handbook offers sufficient proof of the usefulness of such a work. Although the author has not entirely rewritten this book, he has introduced many alterations, rearrangements and additions which enhance its usefulness. The section on development of the embryo, which appeared in the first edition, has been omitted from this edition, as it was not considered to come within the scope of the subject treated. The writer has used the book as the basis of his lectures for the past ten years, and has in this edition made use of all the suggestions which have occurred to him in this continuous use of the text during that time.

PORTFOLIO OF DERMOCHROMES. By Professor JACOBI of Freiburg im Breisgau. English Adaptation of Text by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, London. New York: Rebman Company, 1903.

THIS is the second volume, concluding the work, of Jacobi's "Dermochromes," the first volume of which was reviewed a few months ago in these columns. The work contains plates beautifully produced in natural tints by a new process, illustrating the common diseases of the skin, including the syphilides, which the general practitioner has frequent opportunities of observing in his practice. Each plate is accompanied by a page or more of explanatory text containing practical points in treatment. In the first volume most of the plates were taken from models in Neisser's clinic in Breslau, but for the illustrations of diseases treated of in this second volume, the author has made a wider selection, borrowing not only from Neisser's Clinic, but also from the Freiburg Clinic, Lesser's and Lassar's Clinics in Berlin, Neumann's and Kaposi's in Vienna, and the Hôpital Saint-Louis in Paris. Fourteen of the forty-four plates are given to a depiction of the various lesions of syphilis. Other interesting subjects of illustration in this volume are acne, drug eruptions, nævi, eczema, and scabies. The plates are of the same degree of excellence as those in the first volume, and we can only repeat, with added emphasis, what we said in speaking of the first part, that the work is admirably adapted to the use not only of the professional dermatologist, but also of the non-specialist or the student who has not the time or the opportunity to study the subject deeply, but who would yet wish to be able to treat, or at least to recognize, the more common dermatoses met with in daily practice.

OSSERVAZIONI SU 203 CASI DI CROUP CURATI ALL' OSPEDALE COTUGNO; E su 80 Intubazioni Eseguita dal Prof ALFONSO MONTEFUSCO. Docente d'Igiene nella R Università di Napoli. Napoli: Detken & Rocholl, 190

THIS review of one hundred and seventeen cases o pharyngeal diphtheria and two hundred and three cases o diphtheritic laryngitis does not afford much of interes except the value that always attaches to extensiv statistics of any disease. In the present instance th observations suffer somewhat through the fact that th diagnoses were not based on bacteriological examination Serum therapy, intubation, and trachectomy were em ployed in the customary manner and the total mortalit was 29.5 per cent.

ANATOMY APPLIED TO MEDICINE AND SURGERY. By I E. MUNDELL, B.A., M.D. Professor of Applie Anatomy, Faculty of Medicine, Queens Universit etc. Kingston: Printed at the British Whig.

IN spite of the large number of books, similar to this o in scope and general treatment, which have been appea ing during the last few years, the present volume w probably find many appreciative readers. Efforts inject a little life into the dry-as-dust-iness of anato have always been welcomed by students of all generation and the author has incorporated enough clinical materi into his rather sketchy sections on the anatomical regio of the body to make their perusal easy and profitabl The book can never hope to afford more than collater reading, however, owing to its incompleteness, and suffers through the absence of adequate illustrations a the presence of poor press work and innumerable m prints.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. New Edition, Completely Revised and Rewritten. Edited by Albert H. Buck, M.D. Volume VII. Illustrated by Chromolithographs and Six Hundred and Eighty-eight Half-Tone and Wood Engravings. New York: William Wood & Company, 1904.

The titles in this, the penultimate volume of the work, run from "Saccharin" to "Ulcer," and include some of the most important subjects in medicine. Among the more noteworthy articles are those on sarcoma, scarlet fever, sewerage and sewage disposal, the sexual organs, the skull, smallpox, the spinal cord and spinal-cord diseases, the spine, the spleen, the stomach and its diseases, the sympathetic nervous system, syphilis, the teeth, teratology, thymus and thyroid glands, the tongue, tracheotomy, transporting the disabled, tuberculosis, typhoid fever, typhus fever, and ulcers. The contributors number one hundred and twenty-five and they hail from all sections of the United States and Canada. The articles are evidently for the most part the outcome of study and careful preparation, and all the important ones bear internal evidence of original work and of being written from the author's own knowledge and experience, and not simple compilations. Thus one who consults the work has the feeling that he is taking counsel of a practical man, of one who knows whereof he speaks and can give reasons for the faith that is in him—and there are few articles which the reader can peruse which will not give him new facts or new ideas to add to his store of medical knowledge.

Textbook of Operative Surgery. By Dr. Theodore Kocher, Professor of Surgery and Director of the Surgical Clinic in the University of Bern. Authorized Translation from the Fourth German Edition by Harold J. Stiles, M.B., F.R.C.S.Edin., Surgeon to the Royal Edinburgh Hospital for Sick Children; late Asst. Surgeon, Edinburgh Royal Infirmary; Examiner in Anatomy, Royal College of Surgeons, Edinburgh. London: Adam and Charles Black, 1903.

It is quite out of place for any words of general praise to be bestowed upon this magnificent product from the pen of one of the world's greatest surgeons. The American spirit of cut first and diagnosis after, is, in this book of technique, distinctly wanting. Nevertheless, it may not be amiss to call attention to the very obvious neglect with which in certain cases American works have been treated. If lack of pathological austerity is an American fault, this failure of recognition is distinctly its Teutonic brother. On page 5 the author discusses medullary anæsthesia. He states that "Birr conceived the ingenious idea of rendering a large number of nerve trunks (even the spinal cord itself) insensitive by injecting the lumbar subarachnoid space." This is an error, for while in 1899 Birr and Tuffirr, independently, popularized the method by demonstrating its practical utility, Corning of New York "conceived the ingenious idea" above referred to, in 1885. To the chapter on the abdomen so much has been added that it has practically been rewritten. Detailed attention is given to the author's method of cure for inguinal hernia, for which he claims 100 per cent. of permanent cures!! Very decidedly, Kocher has the courage of his convictions. Any reader who can forgive this self-praise and who wishes to know the underlying pathology rather than the mere technique of operations will find the volume of great value.

Operationen am Ohr, Die Operationen bei Mittelohreiterungen und ihren intrakramillen Complicationen. Für Ärzte und Studierende. Von Dr. B. Heine. Berlin: S. Karger, 1904.

This monograph is an exposition of the present status of surgical otology. Part I discusses operations on the membrane, tympanic cavity and mastoid, and the opening of the labyrinth. Part II operations for extra- and subdural abscess, diseased condition of the cerebral blood-vessels, brain abscesses and meningitis, all with reference to their origin from aural lesions. It is well printed and the text is well paragraphed. Special commendation must be given to the half-tone plates, which are unusually clear and distinct. The sub-headings under the various chapters convey most forcibly an idea of the vast progress made in otological surgery within the last few years. Detailed information is given of the after-treatment of the various procedures described, a matter in which textbooks are often faulty, a too generous estimate being often made by authors of the reader's knowledge.

Das Röntgen-Verfahren, mit besonderer Berücksichtigung der militärischen Verhältnisse. Von Dr. Strehow, Generalarzt und Korpsarzt des X. Armeekorps. Berlin: August Hirschwald, 1903.

As its name implies, the scope of this work is mainly limited to the technique of production of the *x*-ray. Its main object is to show the usefulness of the ray in making diagnoses and the description of apparatus best adapted for military purposes. As such, it is an extremely valuable addition to *x*-ray literature, inasmuch as the thorough manner in which the different portable apparatus, especially designed for rough-and-ready usage in time of war is dealt with, is, perhaps, found in no other work of to-day. It is not of as much use to the general *x*-ray worker, who is, perhaps, equally interested in the ray as a therapeutic agent as an aid to surgical diagnosis. As an almost exhaustive treatise on the method of ray production, especially for military use, it will interest many.

Transactions of the Clinical Society of London. Volume the Thirty-sixth. London: Longmans, Green & Co., 1903.

The present volume comprises the proceedings of the society from October, 1902, to May, 1903. Forty-two papers are presented, and the list of essayists includes some of the best known English clinicians and surgeons. The interest of the communications is well up to that of previous issues, and the volume reflects the progress of the times in a most satisfactory manner.

The Hospital Formulary of the Department of Public Charities and the Department of Bellevue and Allied Hospitals of the City of New York. Sixth Revised Edition. W. E. Dreyfus, A.B., Ph.D., Editor, New York, 1903.

It is to be regretted that the edition of this revision of the Formulary of the Department of Charities has been limited to a number which makes it impossible to supply copies to physicians or pharmacists outside of the department, for it would prove a most serviceable guide to all interested in the preparation or administration of drugs. The revision has been most painstaking, and among the additions are many of the working formulæ of the General Drug Department, together with an index of diseases which should prove very helpful.

Beiträge zur Experimentellen Therapie. I. Aetiologie und aetiologische Therapie des Tetanus. Von E. V. Behring. II. Neue Mittheilungen über Rindertuberculosebekämpfung. Von Dr. med P. H. Römer. Mit 33 Tafeln. Berlin: August Hirschwald, 1904.

These two communications comprise technical and theoretical considerations on the action and production of tetanus antitoxin, and a product for the immunization of cattle against tuberculosis. They are, however, too complex for summarization in brief.

Nervous and Mental Diseases. By Archibald Church, M.D., Professor of Nervous and Mental Diseases and Medical Jurisprudence in the Northwestern University Medical School (the Chicago Medical College), Chicago; Late Professor of Neurology in the Chicago Policlinic; Neurologist to St. Luke's, Wesley, Mercy, and Chicago Hospitals; Consulting Neurologist to the Home for Destitute Crippled Children, Chicago; and Frederick Peterson, M.D., President of the State Commission in Lunacy, New York; Chief of Clinic, Department for Nervous and Mental Diseases, Columbia University; Instructor in Mental Diseases, Columbia University; Ex-President of the New York Neurological Society; General Consultant to the Craig Colony for Epileptics. Fourth Edition, Thoroughly Revised. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

This book is not the joint creation of two authors working in collaboration, but is really two treatises bound in one volume. The treatise on nervous diseases is written by Dr. Church, that on mental diseases by Dr. Peterson. The work made its reputation in the first edition, and subsequent revisions have merely kept it abreast of the times without materially changing its character, except, of course, that deficiencies have been supplied and other necessary changes have been made, all naturally tending to improvement. In this new edition the principal additions are in relation to the healing of nerves, the diagnostic value of astereognosis and Kernig's sign, intermittent limping, herpes zoster—a disease claimed by the neurologist as in his domain rather than that of the dermatologist, and the healing of nerves. In the division treating of mental diseases the chief addition is a section prepared by Dr. Adolph Meyer, giving a critical review of the work of German investigators in psychiatry, the result of which has been to modify so strikingly the accepted views on this subject.

The book is handsomely gotten up and the illustrations are well executed and come out well on the glazed paper used. But by reason of this glazed paper the eyes of the reader are sacrificed to the beauty of the illustrations, and no one could use the work as a textbook, reading in it for long stretches of time, without seriously tiring the eyes. The book is also too big and too heavy to be of service for anything more than a work of reference. For this purpose it can be recommended.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 28, 1903.

WENDELL C. PHILLIPS, M.D., PRESIDENT.

Abdominal Surgery in Young Children.—This was the special topic for the evening.

Intussusception and Appendicitis.—Dr. JOHN F. ERDMANN presented this, the opening paper of the series. He said that he was becoming more and more convinced that operation should be promptly resorted to in intussusception instead of temporizing with air inflation, hydrostatic pressure, and similar measures. It should be noted that sudden abdominal pain was usually the first symptom. In the first hour or two the abdomen was relaxed and no tumor could be felt unless the intussusception was of considerable extent and was taking place rapidly. After a few hours abdominal distention and evidence of intestinal obstruction were present. In 60 per cent. of the twenty-six cases which he had seen, and upon twenty-three of which he had operated, there was no tumor palpable either through the abdomen or per rectum. When a tumor was present, it was not usually sausage-shaped, as stated in the books, but round and nodulated. The great danger of reduction by injections was that the greater part of the intussusception might be reduced with a temporary relief of all the symptoms, and still a portion remain unreduced. He would not feel satisfied that reduction had taken place, even though the symptoms were improved, unless the child soon had a movement of the bowel of a character indicating removal of the obstruction. Enemas prior to operation were useful because there could be no doubt that they caused partial reduction, and so facilitated the subsequent operative procedures. It was a significant fact that his greatest mortality rate had been in those cases in which the longest time had been required to effect reduction, and those cases in which the intussusception was of the longest duration. The incision for the operation was always made in the middle third of the rectus muscle, and should not ordinarily be more than two inches at the commencement of the operation. In the eleven cases operated upon since January, 1902, he had removed the appendix before closing the abdominal incision, and in all but one instance the appendix had constituted one part of the intussusception. When the intussusception could not be reduced or gangrene existed, resection and the establishment of an intestinal anastomosis were in order. The abdominal contents should always be examined for multiple intussusceptions. After reduction, the abdominal incision was sutured in the ordinary manner, and a tight abdominal dressing applied. Paregoric should be administered every three hours to control peristalsis, and bismuth should be given along with a fluid diet. There was usually a foul-smelling green diarrhœa after the operation, due to superficial necrosis of the mucous membrane.

Appendicitis.—The speaker referred only on this occasion to cases of appendicitis occurring in children not over ten years of age. Since January, 1902, he had seen 257 cases of appendicitis, and had operated on 201 of them. Of this number twenty-nine were in children under ten years. Twenty-two of these children were operated on, with two deaths. All of the cases were acute. Nine were operated upon in the primary attack. The appendix was removed in every instance. Fourteen cases were drained. In two cases a mass of pin-worms constituted the foreign body in the appendix. The cases not operated upon could not be traced, so that the termination was not known. The McBurney incision was used in sixteen cases. The stump was inverted four times after the method of Dawbarn, and in the others it was tied off and cauterized with pure carbolic acid. The diagnosis in such young children was difficult because one must rely upon subjective symptoms largely and the statements of the mother or attendant. One should, however, be able to exclude intussusception after a careful inquiry into the history. He had seen the abdomen opened, and had opened it himself for a supposed appendicitis when the true diagnosis proved to be pneumonia. Pain, as shown by crying, together with fever, restlessness, sleeplessness, and abdominal tenderness, were the chief symptoms to be relied upon at first for the diagnosis. Almost unconsciously these little patients would place the hand over the region of the appendix to guard against any manipulation of this region. The McBurney incision was used when no mass could be felt, while the Kammerer or the split-rectus incision should be employed when the mass was more to the median line or down in the region of the bladder. When free pus of the serous variety was present in the general peritoneal cavity, he sponged out the cavity as dry as possible. Several years ago he gave up the plan of irrigating the general peritoneal cavity. When drainage seemed requisite, he usually made use of a "cigarette" drain. A movement of the bowel should be secured in the first twenty-four hours ofter the operation. He usually gave $\frac{1}{10}$ grain calomel triturates as soon as the vomiting induced by the anæsthetic had ceased. Immediately after the operation an enema of a solution of sulphate of magnesium was administered. If no drainage were employed, the patient was allowed to sit up on the fourth day, and was out of bed on the seventh day.

Abdominal Incision for Tuberculous Peritonitis.—Dr. SAMUEL LLOYD read this paper. He said that he knew it to be a fact that a certain number of these cases recovered without operation, and that it was equally true that a certain number were not benefited by operation. One of the difficulties to be contended with by surgeons was the late period at which these cases were referred to them for operation. As a general rule, the onset of a tuberculous peritonitis was, or seemed to be, rapid, although it was probable that the tuberculous deposit was present a long time before the symptoms became sufficiently urgent to require surgical interference. Localized tuberculosis of the peritoneum was usually discovered accidentally in connection with the search for some other condition believed to be present. It was not always possible to differentiate between an appendicitis and a tuberculosis in or about the ileocæcal valve. He did not consider it worth while to operate upon any patient who had marked pulmonary tuberculosis or gave evidence of a general tuberculosis. On the other hand, in cases of acute miliary tuberculosis he thought great benefit might accrue from an abdominal incision and washing out of the whole abdominal cavity with a full-strength solution of hydrogen peroxide. It was remarkable how each tuberculous nodule would stand out prominently after this application. It had been his good fortune to reopen the abdomen in two cases subsequent to this operation for tuberculous peritonitis, and he had found absolutely no trace of the former peritonitis at the second operation. Fecal fistula was a common result after tuberculous peritonitis. In these cases of miliary tuberculosis he believed the operation should be done as soon as the diagnosis could be made. The onset was sudden, the progress rapid, and the accumulation of fluid so great as to give rise to great dyspnœa. With this there was rapid emaciation. By operation, the fluid was evacuated and an opportunity afforded for washing out the abdominal cavity with the solution of hydrogen peroxide. If the wound were left open, as he preferred in all cases, it prevented a second distention of the abdomen, and favored a marked improvement in the patient's general health. In the cases of chronic caseous or ulcerating tuberculosis the performance of the operation would depend largely upon the seat of the disease and its extent. If only a small number of isolated intestinal glands were involved it might be possible markedly to benefit, or even to cure, the patient. In the cases of chronic fibroid tuberculosis he did not believe surgical interference was advis-

able. Out of twenty-one cases of miliary tuberculosis of the peritoneum that he had been able to look up for this paper, seventeen were practically cured at the time of leaving the hospital. His own opinion was that the operation for tuberculous peritonitis afforded the patient an opportunity to gain in strength and nutrition which would not be possible under any medicinal treatment.

Pyloric Stenosis.—Dr. J. G. WILLIAM GREEFF read this paper. He said that he had come to the conclusion that the cases reported as congenital pyloric stenosis were really instances of an acquired stenosis. As yet nothing was definitely known as to the origin of this condition. Almost all authors were of the opinion that it was congenital, and Henschel believed that it could occur in a family showing an evident tendency to hypertrophies. A number of names had been reported which had recovered, and the symptoms presented in these cases were very much like those of chronic intestinal catarrh. Dr. Greeff reported a case that he had personally observed in which it had been possible for him to make the diagnosis *intra vitam*. When first seen, the child was three weeks old, was emaciated and vomited after almost every meal. The stomach was very much enlarged and the greater curvature was three finger-breadths below the umbilicus. The stomach was washed out daily, and the diet suitably regulated. Under the internal administration of nitrate of silver the quantity of mucus diminished but the vomiting persisted. The vomiting continued even after a wet-nurse had been secured This vomiting usually occurred immediately after feeding and in great gushes. It began two weeks after birth. The child steadily lost weight, until, at its death, it weighed six pounds. It was because of the poor general condition that the speaker had not favored operation, although he had made the diagnosis of pyloric stenosis quite early. The operation was finally done by Dr. W. T. Bull with the sanction of Dr. Holt, who concurred in the diagnosis. The operation revealed a thickened mass, 2.5 cm. long and 1.5 cm. in diameter at the site of the pylorus, the boundaries of the tumor being well defined. A posterior gastroenterostomy was done, but the child died twelve hours later from shock. At the autopsy the intestine throughout was found very small. The stomach measured in its greatest diameter, between the cardiac extremity and the pylorus, 12 cm., and between the smaller and large curvature, 7 cm. Microscopically, the mucous membrane showed signs of catarrhal inflammation. The stomach wall throughout was hypertrophied. This was very marked at the pylorus, and a very small probe could hardly be passed through the pylorus. This thickening of the pylorus was plainly due to a muscular hypertrophy. The microscopical examination confirmed these findings. The fibrous tissue surrounding the glands was hypertrophied. The muscular and connective tissue layers were in a condition of pronounced hypertrophy and hyperplasia. The speaker said that the mild cases of this disorder would recover without operation under appropriate treatment. If such treatment failed, it was well, after careful observation for a period of two or three weeks, to consider the advisability of an operation. He did not personally think operation should be advised unless this was done very early indeed, yet it was just at this time that very few felt like taking the responsibility of deciding the question of diagnosis and operation. Through chemical influences it was possible for increased working of the pylorus to take place, thus leading to consecutive hypertrophy and stenosis.

Hernia.—Dr. WILLIAM DE GARMO read this paper. (See page 251).

Dr. A. JACOBI opened the general discussion. He said that appendicitis was a very frequent disease in children and infants, and there were anatomical reasons for this. The appendix of the new-born was one-tenth the length of the colon, while that of the adult was one-twentieth the length of the colon. The appendix continued to grow up to the thirteenth year, both in length and width. After this time it began to atrophy, and about the fifteenth year might even be smaller than at birth. The appendix in the young was very wide, so that it was easy for an accumulation of fæces to take place. The muscular layer was very well developed in some children, and, hence, in them, after a severe colic, the fecal accumulation would be expelled. Not so, however, in children of lax fiber and weak muscular tissue, and, consequently, this class of children were apt to come into the hands of the surgeon.

He saw no reason why some cases of pyloric stenosis might not have an anatomical basis, even though the great majority were functional. Complete obstruction was either the result of inflammation or an arrest of development. The normal diameter of the pylorus was 6 mm. at birth, and it increased one-quarter of a millimeter with each month. There was certainly a congenital hypertrophy of the circular layers of the pylorus, as had been reported many years ago by Hirschsprung of Copenhagen. Dilatation of the stomach might be followed by that of the œsophagus, yet dilatation of the stomach was not so frequently seen as might be expected because of the early onset of vomiting. Death followed frequently within a few weeks or months. A congenital spasm certainly existed, a spasm which was comparable with rectal tenesmus or vaginismus. The few cases that he had seen that had terminated favorably were those in which there had been persistent vomiting and hyperacidity. The latter could be controlled by the administration of alkalies and washing out of the stomach. Henry Ashby's conclusions, both from a large personal experience and from a study of the literature were, that the ordinary form of congenital stenosis of the pylorus was associated with a hypertrophic condition of the pyloric sphincter; that the essential feature was a spasm of the sphincter; that there was usually a secondary hypertrophy of the walls of the pyloric orifice of the stomach; that the mild cases might recover under dietetic treatment; that serious cases required some operation, preferably dilatation of the pylorus. When these children could not retain food they must be fed by the rectum, not only being given food, but large quantities of water.

Dr. WALTER LESTER CARR, referring to the operative treatment of tuberculous peritonitis, said that opinion was by no means settled as to the value of the operative treatment of this condition. No doubt, where there was marked ascites the operation would give prompt relief. Some authors had reported very much better results from medical treatment. We should take the position that we were dealing with an infection, and that if the systemic infection were not too great it might be allowable to operate; in any case he believed that an exploratory laparotomy was unobjectionable.

Dr. MARK I. KNAPP said that the cause of the pyloric stenosis was invariably mechanical, but it had not been shown that the condition was present at birth, although it was known to exist a few weeks after birth. The growing child would respond very easily to stimulation, and in this instance the stimulation was largely chemical, although to some extent mechanical. The same cause which gave rise to peristalsis produced the hypertrophy and stenosis, the difference being that in the case of intestinal peristalsis there was a canal of large lumen, whereas in the case of the pylorus of the infant the canal was very small and easily obliterated.

Dr. Jacobi called attention to the fact that the stomach of the new-born infant was very little more than a dilated œsophagus. The two curvatures were not so developed as in the adult, and the stomach was a mere pouch hanging nearly vertically.

Iodides per Rectum.—For patients in whom the internal administration of iodides produces gastric disorders, v. Zeissl advises its administration per rectum. He uses sodium or lithium iodide ℥ss to water ℥i with 5 minims of laudanum injected through a Nelaton catheter.—*Die ärztliche Praxis.*

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held December 15, 1903.

LEWIS A. CONNER, M.D., IN THE CHAIR.

Malignant Endocarditis of the Tricuspid Valve with Perforation of the Interventricular Septum.—Dr. LEWIS A. CONNER presented this specimen. The patient was a male, twenty-four years old, born in Hungary, and was admitted to the hospital October 30, and died November 20, 1903. He gave no history except illness for two days with fever and chills. His temperature was very high, and septic in character. The leucocytic count was 19,200. No physical signs were found. Five days later a faint systolic sound was noted, and a systolic murmur over the lower half of the precordium. The murmur grew louder and harsher. Its maximum intensity was midway between nipple and the sternum. There were no signs of pulmonary emboli. Two blood cultures gave pure growth of a diplococcus resembling the gonococcus. A bacteriological examination of smears taken from the urethra was negative. The patient had a persistently high temperature, and high leucocytosis, became rapidly anæmic, and died three weeks after admission.

At the autopsy the heart was found to be moderately enlarged, weight about fourteen ounces, with muscle yellow, soft, and friable. The pulmonic and mitral valves were normal. A large and ragged thrombus was found on the tricuspid valve with ulceration and extension through septum at the base of the aortic cusp. The aortic cusps were involved. The lungs were congested, and œdematous, but no infarcts were found. In the spleen there was found one small infarct. There was a parenchymatous nephritis. He called attention to the following features: (1) Absence of signs of tricuspid obstruction. (2) Absence of pulmonic infarctions. (3) The obscure etiology.

Melanosarcoma of the Liver.—Dr. LEWIS A. CONNER presented this specimen, which was removed from a patient fifty-four years old, a waiter by occupation, who died November 20, 1903. He had been a hard drinker. He had jaundice twenty years ago which lasted two weeks; otherwise he claimed that he had always been well. Symptoms of his present trouble began six weeks before admission, when he had severe pain in the epigastrium. He lost flesh. Two days prior to admission he began to vomit. The pain, vomiting, and emaciation continued until he died of exhaustion one week after admission.

At the autopsy the liver was found to be hard and nodular, the mass filling almost the entire abdomen. It weighed ten pounds and eleven ounces, was greenish-black in color, with many small yellowish-to-white nodules. Upon section there were myriads of small nodules, yellowish-white, or black. The right suprarenal showed a black nodule the size of a pea. Miliary metastases were found in the right auricle and mucous membrane of the stomach, in the bladder, in the pleura, pericardium, and peritoneum. A careful search of the skin and mucous membranes failed to reveal scars, nævi, or primary growth. He called attention to the following features: (1) Size of the liver. (2) Many miliary metastases. (3) Difficulty of detecting the primary growth.

Fatal Hæmatemesis from Perforation of the Œsophagus by a Latent Thoracic Aneurysm.—Dr. LEWIS A. CONNER presented this specimen, which was removed from a patient who died December 2, 1903. The patient had been well until two or three days prior to admission, when he developed a slight cough, and pain in the left side of the chest. There was no dysphagia. He began to vomit large quantities of blood, but the vomiting ceased after admission only to begin again twelve hours later, just before his death. Examination of patient's chest was negative. When he died he evidently was exsanguinated.

At the autopsy no marks of cutaneous syphilis were found. The stomach was found to be distended with 1300 c.c. of blood. The heart was moderately hypertrophied and weighed twelve ounces. The aorta was very much dilated and sclerotic. An elongated sacular aneurysm of the descending arch of the aorta was found which extended from the beginning to just above the diaphragm. It had perforated the œsophagus, causing a fatal result from hemorrhage.

Dr. MORRIS MANGES reported a primary case of melanosarcoma of the liver that he saw twelve years ago, the history of which was somewhat similar to the one related by Dr. Conner. The rapidity of its course was a very striking feature. The patient was a woman, twenty-six years old, and her liver, within four weeks, increased from a moderate enlargement to one entirely filling the abdomen. This took place in the shortest time he had ever noted; it was impossible to make a diagnosis until one week prior to her death. At autopsy the liver looked entirely different from the one presented; it was melanotic, but more microscopical, than macroscopical. There were secondary cutaneous manifestations, yet the liver itself was not pigmented and yet the microscope showed an enormous invasion. No primary focus could be found, and it was assumed that it was a primary melanosarcoma of the liver.

He recalled one or two cases of mycotic aneurysm of the femoral artery resulting from malignant endocarditis. In one of these he recalled a very peculiar effect. The aneurysm was very small, mycotic in origin (it was the fourth he had seen that involved the lower extremity, and there was much doubt regarding the diagnosis on account of the latency of the phenomena. The aneurysm was found to be very small and out of all proportion to the amount of erosion. He thought there must have been other factors in play than the mere mechanical pressure.

Dr. E. E. SMITH had seen a case similar to the last one reported in which he had examined the blood and stomach contents. The blood showed nothing unusual. After the test-meal the stomach contents showed an increased acidity. The patient gave a history of great pain which had existed for several weeks. The patient was very anæmic and a probable diagnosis of gastric ulcer was made. Soon after entering the hospital there was noticed a thrill over the region of the seat of pain and vomiting of blood. The patient came to operation but nothing was revealed. Soon afterward the patient died and the autopsy revealed a thoracic aneurysm that had eaten into the œsophagus close to the opening into the stomach.

Dr. CONNER asked Dr. Hodenpyl regarding the origin of these sarcomas, if they did not arise from the pigment cells. In the case related he said it was difficult to see how it could have arisen in the liver.

Dr. HODENPYL replied that he had seen cases of melanotic sarcoma of the liver but that they were always secondary manifestations. All those that he had seen originated in the pigment cells of the skin or subcutaneous connective tissue.

Dr. PEABODY asked if there were found petechial hemorrhages in the skin.

Dr. CONNER answered no. He said that although the tricuspid lesion was present the lungs were free from emboli. Before death there had been one or two hemorrhagic areas over the elbow, but these were not in any way the result of irritation or emboli.

Dr. MANGES said that Ziegler spoke of the possibility of primary melanosarcoma of the liver.

The Clinical Value of the Average Analysis of Gastric Contents.—Dr. CHARLES SUMNER FISCHER read this paper. He said that he had been led to a consideration of this subject by a passage in Hemmeter's book in which he states the following: "It would be a valuable contribution

by various gastroenterologists of the United States if they collected and reported the frequency of hyperacidity and other gastric diseases occurring in their localities so as to throw light on the influence of race, climate, geographical distribution, etc.," and again, by a statement of Riegel, "that the determination of the frequency of hyperchlorhydria by statistics will remain impossible so long as every dyspeptic is not examined by lavage and that hyperchlorhydria is found more frequently in private practice than in hospital because the symptoms of this condition are generally not severe enough to send the patients to these institutions." He said that so long as various observers in different parts of the country did not employ the same methods and base their conclusions upon uniformly imposed conditions so long would it be impossible to estimate correctly the actually prevailing conditions and frequency of chronic gastric diseases. He chose the acid secretion of the stomach as a subject for discussion because it was the function about which the most was known and which gave the greatest aid in diagnosis. In the determination of hydrochloric acid the greatest errors of judgment were made. He said the whole question resolved itself into this: Can we get a better knowledge of the gastric acid secretion by employing carbohydrates or proteids as exemplified in the ordinary test-breakfast of Ewalt-Boas or the more complicated meat containing meal of Riegel, or had we better use both of these meals; or would it not be better to discard both of these meals as placing the organ under natural conditions and examine the stomach under the circumstances in which it finds itself and containing the food to which the individual had been accustomed or which has led to his discomfiture?

He reviewed briefly the separate lines of experiments which had been pursued for years and which had a direct bearing upon the question, classifying them as diagnostic, dietetic, and the purely physiological. The first two were closely allied and had for their object the study of the extreme development of the acid secretion of the stomach, and the results that had been obtained in each case were directly interchangeable. The value for diagnostic purposes of the ordinary trial breakfast of Ewald-Boas or the proteid meal of Riegel he said had been variously estimated by different writers. The objections to the test breakfasts were its simple, non-stimulating character, that it was nauseous and did not appeal to the special senses and did not give an adequate idea of the secreting possibilities of the stomach. On the other hand its uniform character seemed to be the quality which appealed most to those who preferred it. The chief objections to the meat-containing meal seemed to be its non-conformity of character and the greater difficulty in manipulating it. Leaving aside the consideration of uniformity or manipulation, the whole subject seemed to resolve itself into a discussion of the stimulating properties of carbohydrates and proteids to gastric secretion. The object of a large part of experimentation had been for dietetic treatment of hyperchlorhydria; but the results obtained could be applied with equal advantages to the question of diagnosis. He said that the controversy in regard to the proper dietetic treatment of hyperchlorhydria began in 1891, and he briefly reviewed various phases of the struggle.

He said that in every case of chronic gastric disease involving abnormal acid secretion, the object of the chemical analysis of the gastric contents was to develop, if possible, the average capability of the stomach to secrete acid and any vagaries of the same which might exist. It was necessary to place the stomach under conditions such as had existed during the period of illness. He asked if that could be done by giving simple tea, without milk or sugar. A partial solution of this problem was found in the results obtained by Pawlow by physiological experiments on the influence of real and fictitious feeding, and the principle impression conveyed by these experiments were that, so far as diagnosis was concerned, any test for the development of the gastric acid secretion was to give satisfactory data for judging the average functional capability of the stomach should appeal not only to the appetite, inducing special senses of sight, taste, and smell, but should also be a direct stimulant to the secretory centers in the stomach walls, for Pawlow demonstrated that the acid secretion during the first half hour of digestion was due to the first, and that the real chemical stimulation began later. In the words of Troller, the test must be a physiological stimulant, and a physical-chemical stimulant. He said that if we accepted the results obtained by clinicians and physiologists, the ordinary trial breakfast did not fulfil the requirements of a physiological test for the acid secretions, and it failed in the following: It failed to excite the appetite, and hence the vagus stimulation in those cases in which it was taken with repugnance; it failed to be a physical-chemical stimulant in that it did not act as an energetic stimulant to the secretory centers located in the stomach walls; lastly, it failed in that it placed the individual in a false condition of life for examination. Therefore it was not surprising that this meal should give a variety of results in clinical work, 50 per cent. of which were erroneous, at least upon the first examination. In taking the statistics from hundreds of cases of gastric analyses in women, three-quarters to one hour after a trial breakfast, he found that 60 per cent. were hypochlorhydric, 30 per cent. normal, and the remainder hyperchlorhydric. In these cases, upon the third examination, he found that 57 per cent. had remained stationary, wereas 43 per cent. had changed as follows: Of the subacid cases, 22 per cent. became normal, and 2 per cent. were even hyperacid; of the normal cases, 14 per cent. became subacid, and of the hyperacid cases, 2 per cent became normal. Among men the changes were not so marked. Taken collectively, among men and women, it was found that 60 per cent. remained stationary, and 40 per cent. changed upon the third examination. He stated that long ago he came to the conclusion that first examinations should be excluded in all cases as being entirely unreliable; there were too many disturbing factors which were likely to influence gastric secretion, such as misunderstanding on the part of the patient as to the time and the food, and most of all, such factors which related to the emotions, such as anxiety, uncertainty, and fear. Upon second examinations these were largely removed. The variations could not be attributed to nervous influences, for neuroses were excluded from the list. There remained but one conclusion, that the ordinary trial breakfast did not fill all the requirements of a reliable test for the gastric secretions. This, he said, was not surprising when one recalled the experiments of Pawlow. In order to obviate the objections to the test breakfast, some authors advised administering proteid in some form; this, he said, would act either as an energetic stimulant to the acid secretion in cases in which subacid conditions were due to continuous overstimulation, or it would act as a neutralizing agent when hyperacidity was the result of gastric irritability of an intermittent nature. In order to obtain uniform results as nearly as possible according to the ideas of Bushman, and in order that the results might be traced directly to the influence of the proteid, and in order to demonstrate more closely the difference between a proteid and carbohydrate diet for purposes of diagnosis, he said he had discarded the ordinary meal as proposed by Riegel, and simply employed the ordinary test breakfast of Boas, plus the addition of one-quarter of a pound of lean, finely chopped beef, prepared by boiling, and slightly seasoning to make it more palatable. In the examination of hundreds of cases he had found the results were more constant; of the cases examined, 40 per cent. were subacid, 46 per cent. were normal, and 14 per cent. were hyperchlorhydric upon the second examination. Upon further examination it was found that 35 per cent. remained subacid, 54 per cent. remained normal,

and 11 per cent. remained hyperchlorhydric. Comparing this with the results obtained by the trial breakfast, the number of subacidities were reduced 23 per cent., the normal acidities increased 15 per cent., and the hyperacid cases increased 9 per cent. He then gave a few examples to demonstrate the necessity for some analytical reasoning for the proper judgment of any case of chronic gastric disease. The mere presence of so much acid in the stomach at a given time would be of small value for this purpose, and he said the older practitioners were justified to a certain extent when they looked with distrust upon gastric analyses in general. Unless the average capability of the stomach to secrete and work was developed by the examination, he believed it would be far better to depend for diagnosis and treatment upon clinical experience and a good history. It was impossible to do this by giving one meal; hence it was impossible to discard either carbohydrates or proteids among people who had been accustomed to a mixed diet, especially if one intended to bring the diagnostic method into line with the physiological observations of Pawlow. Sometimes it would happen that one was unable to obtain results which would throw light upon the real nature of the disease, and the reason for this might be that the examination was carried out under conditions unnatural to the organ; to give bread and tea, or plain unseasoned meat, was unnatural. He said that many patients who appeared for treatment were in an almost starved condition, and it was not reasonable to expect a starved organism to produce results of digestion indicative of its capability. If more scientific and simpler methods have not yielded satisfactory results, he then examined them some hours after they had enjoyed a satisfactory meal. In this way obscure cases were often suddenly rendered clear. He said this was best seen in the rarer forms of chronic gastric conditions, such as those occurring periodically and affecting the secretory or the motor functions. If they are suffering, he said, it was so much the better, for then one could more likely get at the cause of the suffering.

Dr. GEORGE L. PEABODY said that it was especially important to consider the results of gastric analyses as only a part of the means of making a diagnosis. He did not think it was fair to attempt to make a diagnosis of gastric carcinoma, for instance, in the absence of physical signs, solely upon gastric analyses, although one must admit such to be a very important factor in diagnosis. Because there was a persistent absence of free hydrochloric acid, and the presence of lactic acid, where there were no marked loss of weight and absolutely no cachexia, he said that few would be willing to say that was sufficient to base a diagnosis of gastric carcinoma, whereas the existence of facts derived from repeated gastric analysis would naturally lead one to think that its existence was only probable. The New York Hospital had provided him with histories of a few cases occurring there, of which the following was a brief summary.:

CASE I.—This was a woman, twenty-seven years old. Repeated analysis of the stomach contents showed the absence of free hydrochloric acid and a trace of lactic acid. She had vomited blood several times, and had passed some per rectum. She had lost fifty or sixty pounds, but was not cachetic in appearance. He said all must admit that her age was against the existence of gastric carcinoma, but that the analysis of the stomach contents rather pointed to it. An operation was deemed advisable, and there was found a tight pylorus and a gastric ulcer. A pyloroplastic operation was done with a marked improvement in the condition of the woman.

CASE II.—This was a woman, thirty-three years old. After the administration of the test breakfast, in one hour the stomach was always found to be empty. When examination of the contents in less than one hour there was found a complete absence of free hydrochloric acid, and a trace of lactic acid. In this case there was no suspicion of gastric carcinoma. This patient was now receiving hydrochloric acid with her meals. During the past ten days she had gained four and a half pounds in weight. She suffered from gaseous distension. In the urine occasionally casts were found and a trace of albumin. There was a high arterial tension.

CASE III.—This patient was a man, thirty-one years old. The gastric contents showed no free hydrochloric acid and no lactic acid. He had had symptoms for one year past, and during the last six months constant gastric symptoms. He lost some weight. There was no cachexia, no tumor, nor any appearances of gastric carcinoma, from which he suffered.

CASE IV.—This patient was a woman, sixty years old, who appeared as though suffering from a chronic gastritis. Her teeth were defective, and this was probably the cause of the irritation from which she suffered. Hyperchlorhydria was always present. Improvement occurred when the diet was regulated. He said a person, sixty years old, with persistent pain, loss of weight, persistent gastric symptoms, etc., would be considered a sufferer from gastric carcinoma.

He said that frequently one was confronted with the difficulty in making a diagnosis between hyperchlorhydria and gastric ulcer. As already stated, there was no other way of making a diagnosis except as a result of treatment. He referred to one case in which a diagnosis of gastric ulcer was made. Free hydrochloric acid increased in two examinations. There was free and copious vomiting of blood. The patient was transferred to the surgical ward, operated on, but no gastric ulcer was found. In talking with surgeons and asking them whether they considered visual exclusion as satisfactory evidence of the absence of gastric ulcer, he found that they considered it positive evidence of its absence. Dr. Peabody begged leave to differ with them. He believed that it required a more thorough examination of the gastric mucous membrane than was consistent with life. In the case referred to above none was found.

CASE V.—This patient was a woman twenty-six years old, who began to have pain in the stomach eight years ago. She had an attack of pain followed by vomiting of blood, nearly one pint, about five years ago; these attacks of vomiting and pain continued up to the present time, usually greater after meals. Physical examination was negative. There was an increase in free hydrochloric acid. An operation was performed and no gastric ulcer found. He thought that vomiting of blood, with pain persistent in character and localized, justified the clinical diagnosis of gastric ulcer when there was an excess of free hydrochloric acid present.

Dr. Peabody had a man under observation who was about fifty years old and who had had persistent gastric symptoms, pain, vomiting, great distress, emaciation, these symptoms lasting for more than one year. Recently a gastroenterostomy was performed upon him for a tight pylorus which was very much thickened. He had a dilated stomach. No gastric carcinoma was found. The effect of the operation was most satisfactory, the patient gaining in weight constantly. He referred to one other case of a woman who came under his observation two years ago. She was admitted to New York Hospital with a diagnosis of gastric carcinoma. She lost forty pounds in weight during the year previous. A gastroenterostomy was performed for carcinoma of the pylorus. For two years she led a life of comfort and regained the forty pounds lost. He said she was now in the hospital with periodic attacks of pain which had no relation to her former trouble. This pain lasted eight or ten days and her temperature rose from normal to 103° to 104°; as the pain subsided the temperature returned to the normal. No tumor could be felt. He interpreted her condition now as one of local peritonitis. He believed the carcinoma was recurring and, as it grew, caused attacks of peritonitis with adhesions from time to time.

He said he laid great weight upon gastric analyses in

did not think it wise to give too much weight to them. He believed there was a tendency at the present time, especially for young practitioners, to lay too much weight upon exact methods of diagnosis to the exclusion of all other methods. Some men would not make a diagnosis of typhoid fever unless the Widal reaction was present, or of tuberculosis unless the tubercle bacilli were demonstrated. The same held true regarding gastric analyses. This examination he believed to be a factor of great importance, but it was not fair to exclude all other methods. Only two weeks ago he had a case in which there was evidently pyelitis of the left side. The urine showed the presence of tubercle bacilli, according to the pathologist's report. The pelvic organs were not involved. Under rest the patient got entirely well and all symptoms subsided. In this case there was probably a mistake in the pathologist's report.

Dr. GEO. ROE LOCKWOOD believed that the discrepancies regarding the frequency of hyperacidities were the result of different methods employed by various observers, and also depended much upon the personal equation of the observer and what he considered to be hyperacidity. In New York the normal acidity of from 50 per cent. to 60 per cent. was considered to be a fair average after the Ewald test breakfast. He believed it to be as difficult to make a diagnosis of gastric disorder without an examination of the gastric contents as it was to diagnose a cardiac disorder without listening to the heart. He said he would not treat a case of gastric disorder to-day without being given the privilege of making a test breakfast, and during the years he had had only one who refused to consent to it. He emphasized the importance of ocular inspection of the test breakfast; he relied much upon the eye for a diagnosis with congo-paper; he thought well of the Ewald breakfast on account of its simplicity. Gastric analysis of itself was of little value and should be combined with a physical examination of the patient to detect something of a pathological import, such as the enteroptolic habit as an index to the neurasthenic state, etc.

Dr. WILLIAM ARMSTRONG said he was not so much in favor of the test breakfast as was Dr. Lockwood, and that if we were limited to three or four examinations we could gain more from the Riegel test than from the test breakfast.

Therapeutic Hints.

Induction of Anæsthesia in Prostatic and Renal Surgery.—Mark, reasoning from the evidence adduced for and against the method of subarachnoid injections of cocaine, believes that the following conclusions are justified: (1) That the method is as safe as, if not safer than, general anæsthesia. (2) That we may safely employ up to ⅓ of a grain of cocaine without fear of toxic effects. (3) That shock, when present, is decidedly less than that of general anæsthesia. (4) That it is attended with no danger of annoying sequelæ and symptoms. (5) That on account of the variability in the length of its analgetic action it is contraindicated in prolonged operative procedures.—*Medical and Surgical Monitor.*

The Surgical Treatment of Early Diagnosed Cancer of the Uterus.—J. E. Janvrin concludes that in about one-third of all cases of uterine cancer, involvement of the regional glands in the pelvis takes place. This involvement rarely occurs in the incipient stage, and abdominal radical operation with the removal of the pelvic glands lessens the high percentage of recurrences.—*American Gynecology.*

Medicinal Treatment of Gallstones.—H. Richardson says that glycocholate of sodium will dissolve gallstones in the bladder, and even when cholecystitis is present glycocholate of sodium is indicated not only as a prophylactic but as a solvent for stones already present, and that in those cases only in which there is occlusion of the gall-duct is surgical interference permissible.—*Therapeutic Gazette.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PROSTATIC HYPERTROPHY FROM EVERY SURGICAL STANDPOINT. By Dr. GEORGE M. PHILLIPS. 12mo, 176 pages. Illustrated. Lewis Mathews & Co., St. Louis. Mo. Price, $1.75.

Goundou: Its Relation to Yaws.—A. Nell has met with several cases, and concludes from his observations and inquiries as follows: Yaws bears a causal relation to goundou. In goundou there are symmetrical osteomata on the nasal processes of the superior maxillary bones; they are always congenital, either apparent at birth or to be detected on close examination as faint bosses or ridges; general enlargement in size is always concomitant with body growth, and stops with full adult life. An "acute enlargement" follows or accompanies an attack of yaws; hence some congenital cases are not noticeable if no acute enlargement had occurred, and adults with slight ridges or bosses should be questioned regarding goundou or yaws in the family.—*Journal of Tropical Medicine.*

Treatment of Angina Pectoris.—William H. Waugh treats this disorder by giving glonoin, $\frac{1}{250}$ of a grain every minute until the face flushes. This effect is deepened and prolonged by giving atropine, $\frac{1}{250}$ of a grain, every ten minutes until the mouth begins to dry. There will be no further attack as long as this effect endures, and the effect may be definitely prolonged by repeating the atropine whenever the dryness of the mouth subsides. On the theory that spasm betokens weakness, strychnine, $\frac{1}{180}$ of a grain, every fifteen to thirty minutes, may be administered until the pulse regains its normal tonicity. In the absence of the remedies advised, anything that will bring the tears to the eyes will break the attack. Alcohol in any shape, volatile oils, ammonia, camphor, pepper, ginger, or any other spice or ether given hot and in concentration will answer. In the interval the mental and physical welfare should be attended to.—*Therapeutic Gazette.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 6, 1904:

	Cases.	Deaths.
Measles	852	18
Diphtheria and croup	475	62
Scarlet fever	413	24
Smallpox	5	...
Varicella	108	..
Tuberculosis	347	175
Typhoid fever	24	13
Cerebrospinal meningitis	...	6

Remote Sequelæ of Adenoids.—C. D. Conkey writes that, broadly speaking, adenoids pass away before the child passes into young manhood or womanhood, but that from 5 to 15 per cent. retain their relative size well up into middle life. In regard to the sequelæ, the author recapitulates as follows: Nature often fails to bring relief to the organs of the body influenced by the presence of adenoids, by the shrinking process which take place about the age of puberty. The facial bones are arrested in their development, giving a characteristic appearance to the facial expression which is far from beautiful. The nasal cavities are narrowed by long years of non-use, and are frequently distorted by the development of a high palatal arch encroaching upon their caliber. The habit of mouth-breathing is acquired especially at night, which acts deleteriously upon the ears and upon the respiratory organs. Chronic postnasal catarrh is a frequent accompaniment of adenoids and persists after their disappearance.—*Wisconsin Medical Journal.*

Immunity and Treatment.—Albert S. Grünbaum first briefly outlines some of the phenomena and theoretical foundations of immunity. He then considers a few of the practical applications. The method of immunization, prophylactic inoculation, is well known as applied to smallpox. The reaction produced is generally considered to be a modified form of cowpox, itself a modification of smallpox. The writer thinks a better explanation is given by the hypothesis that vaccine contains the toxini of variola in a toxon condition. It thus immunizes without producing the toxic effects of variola in a similar way to that in which the diptheria toxin leads to immunity. A certain interval elapses before protection is established, and as a result vaccination is ineffectual against smallpox, if done later than four days after infection. The writer believes that the tuberculin cure has been unfairly discredited, and the sanatorium treatment of phthisis unduly extolled. The two together form the ideal treatment. The protection conferred by an attack of the disease or by a process of active immunization (vaccination) is always superior in permanency, and usually in amount, to that attained by the injection of an antitoxic or bactericidal serum obtained from an immunized animal. Organotherapy as a mode of treatment is yet in its infancy, but at least one success has been achieved in the treatment of myxœdema. The popular notion of greater liability to infection during hunger is very probably correct; some receptors are then unoccupied. Susceptibility may be increased by a diminution in the amount of complement. At present we know of no other means of increasing the complement than by inducing a good state of nutrition. The importance of this fact cannot be overrated. Under some circumstances a stimulation to the production of special mediators to anticipate disease may be indicated. As time goes on it will no doubt be possible to extend such prophylactic treatment to the few other diseases which, like smallpox in the past and tubercle in the present, are the chief abbreviators of human life.—*The Practitioner.*

Pathology of Latent Malarial Infection as Observed at Autopsy.—Charles F. Craig confines the term "latent malarial infection" to those cases in which no symptoms are present and no parasites are found on repeated examination of the blood, such cases only being discovered at autopsy. Such cases are rare outside the tropics and the more malarial regions of our own country. Three cases of benign tertian infections and four of estivo-autumnal infections of the tertian type were observed by the author, in which autopsies were performed, most of which had been in the hospital for several weeks. Repeated blood examinations and careful clinical observation had failed to show signs of the disease. The chief point of value ascertained in these cases was that the malarial parasites, either tertian or estivo-autumnal, may be present in the body, may undergo their normal life cycle, without producing symptoms, and that they are practically localized in the spleen. It is probably true that the infected red corpuscles and, to even a smaller degree, the melaniferous leucocytes are not actually confined to the spleen, but are in circulation in the blood in such small numbers as to be practically beyond discovery.—*Journal of the Association of Military Surgeons.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended February 6, 1904:

HEART SYPHILIS,*

BY I. ADLER, M.D.,
NEW YORK.

IT is now generally conceded that there is such a thing as cardiac syphilis—that is to say, that the syphilitic virus can specifically affect the heart. Perhaps O. Rosenbach is the only author who at present disputes this. As soon, however, as we go into details we find a wide diversity of opinion. There is still much confusion as regards the frequency of occurrence of this class of affections, their anatomical and histological characteristics, their diagnosis and clinical manifestations; and this is not strange, for, after all, the entire subject of heart syphilis, as indeed of visceral syphilis altogether, has been a subject of investigation for only a comparatively short time. Barely fifty years have elapsed since the first cases were reported by Ricord (1845), Lebert (1849), and Virchow (1858). Since then much thorough and valuable work has been done on this subject, but a complete and entirely satisfactory knowledge has not yet been attained. Moreover, but very little of all this work has gained admission into the current textbooks, and still less has it reached the consciousness of the medical public at large. It is only very recently that the textbooks occasionally devote to the subject of heart syphilis more than a passing and almost contemptuous notice, while the great majority of practitioners, if they consider it at all, think of cardiac syphilis as a pathological rarity which may occasionally be encountered on the autopsy table, but is of no practical importance. Against this standpoint much has of late been said and written, and it is hoped that the following contribution may assist in convincing the practitioner, not only that syphilis is an important etiological factor in many forms of heart disease, but also that, as a necessary consequence of this, therapeutic possibilities and obligations in our daily practice are opened to us.

Before discussing the clinical aspects of our subject, it will be to the purpose to inform ourselves as to the anatomical lesions which the syphilitic virus is apt to produce in the heart. Three groups of lesions are usually mentioned, viz.: (1) gumma, (2) sclerogummatous arteritis of the coronaries, and (3) fibrous myocarditis. It is generally maintained that these three groups all belong to the so-called tertiary period.

Gumma of the myocardium is of comparatively rare occurrence and differs in no way from the gummata of other organs. It appears to favor the left ventricle and the septum, but may occur in any other region of the heart, especially in the papillary muscles. The gumma may heal and become entirely absorbed, in which case, here, as in every other locality, tough, inelastic, fibrous scar tissue takes its place. This again, especially if at all extensive, may lead to partial distension and dilatation of the heart wall, the so-called cardiac aneurysm, with the imminent danger of rupture. On the other hand, the gumma may break down and ultimately perforate either into one of the cardiac cavities, or, not infrequently, outwardly through the pericardium, causing cardiac perforation and sudden death.

It is impossible to enter here into any, even the most summary, details concerning sclerogummatous arteritis. The very conception of this condition is by no means clearly defined or understood. There is no doubt that gummatous growths can develop in the aorta, the coronary vessels, and also in the smaller arteries in much the same way as Baumgarten has demonstrated for the arterioles of the brain. It is convenient, however, to exclude the aorta entirely from the present discussion, while with regard to the coronary arteries it will suffice to state briefly that sharply defined, small gummatous foci, either singly or in varying numbers, are occasionally found in the course of the ramifications of these vessels. These small gummatous foci may lead to partial obstruction, or even complete occlusion, of the vessels and thus to the suppression of the local blood supply with all its consequences. These processes also belong to the tertiary period.

The fibrous myocarditis or fibrous induration of the heart muscle is usually looked upon as a secondary process, the result of gumma or of obstructive syphilitic endarteritis. Whenever absorption commences in a gumma, fibrous tissue is newly formed to take the place of the absorbed gummatous material, so that when the absorption is finished, a complete substitution of fibrous for gummatous material has taken place. Again, when syphilitic endarteritis has caused obstruction or occlusion of a branch of the coronary artery, it is evident that serious interference with the nutrition of the muscular territory involved must ensue. In consequence of this, myomalacia, degeneration and destruction of muscle fibers, their absorption and replacement by scar tissue follows. While it cannot be denied that these processes do actually occur, usually in the tertiary period, they are, after all among the rare forms of syphilitic lesions.

I desire to call attention to another form of syphilitic myocarditis which does not appear to be generally known. The study of a rather considerable number of hearts of syphilitics of all ages, including both congenital and acquired syphilis, has led me to believe that there is a primary interstitial myocarditis associated with a clearly-defined panarteritis, the so-called arteritis productiva obliterans. This form of myocarditis is probably one of the most frequent occurrences in constitutional syphilis, and is by no means limited to the tertiary period, but, on the contrary, makes its appearance even in very early stages of the disease. It is not proposed to go into details on this occasion. A brief report on the subject was published by me some years ago ("Observations on Cardiac Syphilis," *New York Medical Journal*, October 22, 1898). A few facts, may, however, be here recapitulated: In hearts apparently normal, that show neither functional disturbance during life, nor gross lesions after death, though taken from indubitable syphilitics, it is not unusual to find, especially in the walls of the left ventricle,

*Read before the German Medical Society of New York.

cellular proliferations in the adventitia of the small and smallest arterioles. From these proliferations as starting points, strands of cellular infiltration traverse the neighboring myocardium, the muscle fibers are crowded apart and connective tissue is formed, at first loose and containing an abundance of cells but gradually becoming firm and more and more fibrous in character. The muscle fibers, at first quite normal, gradually degenerate, are atrophied and absorbed, and their place is ultimately usurped by fibrous tissue. Coincident with this process is the extension of the proliferation in the little arteries; the media becomes fibrous, the muscle cells being crowded out and replaced by connective and elastic tissue, and the intima proliferates vigorously. The lumen of the little vessel is more and more obstructed until it is finally entirely obliterated, and the process thus ultimately culminates in the total destruction of the arteriole and the surrounding myocardium, and the substitution in its place of connective tissue gradually becoming more and more densely fibrous. These fibrous patches are, as a rule, but very small, not at all perceptible to the naked eye. In the course of the further development of the process, however, new fibrous patches, sometimes in considerable numbers, continue to appear, and the fibrous tissue invades more and more of the muscular territory until at last quite extensive fibrous degeneration of the heart is produced. It is possible by appropriate treatment to arrest this process at an early stage—as, for example, during the period of cellular infiltration—and thus bring about a practically complete restitution to normal conditions. If fibrous tissue has been formed, the process may, of course, still be arrested and a perfect cure of the syphilitic disease may be effected, but the fibrous tissue once fully formed can never be entirely eradicated, and a complete recovery of normal conditions is, therefore, no longer possible. Some muscular tissue has been irrevocably destroyed and scar tissue has taken its place. To what extent the heart has been permanently damaged will, therefore, depend, in the first place, upon the number and extent of the fibrous patches, and, in the second place, upon their topographical distribution. The various territories of the heart muscle are not everywhere of the same physiological and pathological importance. A fibrous patch buried in the depths of the wall of the left ventricle may be of little or no importance, while a similar patch of the same size and structure located in a papillary muscle will produce disturbances of the gravest consequence. A few very small, possibly microscopical, foci are not likely, therefore, to cause serious damage, while larger and more numerous fibrous patches are certain to deteriorate the functional energy of the heart, even though the syphilitic process has been entirely arrested or completely cured. This is a fact of decisive clinical importance and due to the unique position of the heart in the human economy. A very large gumma of the liver may be absorbed and result in a huge retracted scar and extensive fibrous degeneration of a great amount of liver tissue. Nevertheless, and for all that, the function of the liver need not necessarily suffer. Even in the central nervous system, in an organ as delicate as the brain, syphilitic lesions may cause considerable fibrous degeneration of brain tissue and still, though perhaps associated with more or less brain symptoms, need not necessarily endanger life or the general economy of the system. On the other hand, every damage to the heart muscle must of necessity sooner or later result in serious disturbance of the cardiac functions and, therefore, in great danger to the entire individual. These considerations urge upon us most emphatically the importance of early recognition of syphilitic heart lesions, so that by adequate therapeutic measures the process may be arrested before irreparable damage has been done.

For completeness sake a few words may be added concerning the pathology of syphilitic peri- and endocarditis. The dry form of pericarditis is not infrequently met with, and is usually associated with gumma in or under the pericardium or in the mediastinum. Pericarditis with effusion is probably never directly associated with syphilis. A genuine endocarditis as the result of syphilis is also not adequately proven. Thickening and nodulation of the endocardium occurs together with or as a consequence of gummatous or myocarditic processes. Syphilitic proliferations may be formed on the valves themselves; these can break down and thus, by causing murmurs, simulate the clinical symptoms of endocarditis. Furthermore, not merely relative but very genuine valvular lesions may be brought about by dilatation of the ventricles, by thickening and retraction of the tendinous cords, by myocarditic infiltrations and shrinkage of papillary muscles, by luetic proliferations and their consequences on the valves themselves, etc.

Proceeding now to the clinical aspects of our theme, the first question that presents itself is in regard to the frequency of syphilitic heart disease. I have long ago reached the conviction that cardiac syphilis is by no means a rare disease, but is, on the contrary, quite common. We can obtain but little assistance here from dead-house statistics. Anatomical examinations have always been, and still are, very imperfect with reference to this question. A gumma in the heart is, of course, easily recognized as such, but it will always be difficult to determine if simple myocarditis is of primarily syphilitic origin. The presence of undeniably syphilitic lesions in other organs is often of value for establishing the diagnosis. These difficulties are further augmented when, in the course of time, other lesions, as rheumatic and degenerative processes, have been superimposed upon the old, originally syphilitic myocarditis. The fact, too, that the individual has acquired syphilis in years past must not lead us into the mistake of regarding all pathological changes in the heart of such an individual as necessarily of syphilitic origin. It must be remembered that there is syphilitic heart disease as well as heart disease in syphilitics, and a syphilitic may acquire a rheumatic, a typhoid, or an arteriosclerotic heart lesion as well as any non-syphilitic. There are, nevertheless, certain definite anatomical criteria, upon which it is not necessary to enter here, which will, in most cases, enable us to arrive at a fairly certain conclusion as to the luetic character of a given heart lesion. If more attention be paid in future to the question of syphilis, not only in the gross but also in the microscopical study of heart lesions, we may confidently expect better and more reliable statistics, but even now there are some data which can be utilized. Runeberg informs us in a recent article (*Deutsches medizinische Wochenschrift*, 1–2, 1903) that out of a total of 734 deaths on the list of a single life insurance company, 84 were certainly syphilitics and died of diseases in all probability attributable to lues. Of these 84, 33, or nearly one-half, died of diseases of the central circulatory organs (heart and aorta), and 24 of these 33 died of sudden heart collapse. Grassmann has also made some important contributions to this question (*Deutsches Archiv für klinische Medicin*, Vol. 99). He collected statistics of 288 syphilitics in the early stages of the disease whom he was able to examine very thoroughly and to observe for some length of time. In at least two-thirds of these

cases he observed during the secondary stage, disturbances of the normal heart's action, ranging from very slight anomalies to gravest insufficiency of the heart. In many of these cases the lesions were merely transitory and were readily cured by treatment; in numerous others, however, the heart lesions remained permanent and persistent after the discharge of the patient. His very exact and thorough investigations permit of no doubt as to syphilitic infection being the primary cause of the cardiac affections. These facts assuredly corroborate the view that cardiac syphilis is no rare disease, and we may safely agree with Runeberg that syphilis of the heart is at least as frequent as, if not even more frequent than, syphilis of the central nervous system.

If all this be true, then it necessarily follows that in every case of heart disease it is the evident duty of the physician to take account of syphilis as a possible primary cause, or at least as a contributing factor, for the same reason and in the same way that rheumatism and other infections are thus considered. And here the question of diagnosis arises. Is it possible to recognize heart syphilis as such with any degree of probability? It is a priori quite clear that a syphilitic myocarditis or disease of the coronaries will present no symptoms essentially different from those of the same diseases originating from other causes; nevertheless, there are numerous instances in which the diagnosis of heart disease from syphilis can be established with reasonable certainty, or at least with greatest probability. To this class belong, first of all, certain cases in which manifest affections of the coronary arteries occur in youthful subjects, examples of which have been repeatedly reported and discussed. If, for instance, we find typical attacks of angina pectoris in individuals between twenty and forty years without other evidence of arteriosclerosis or contracted kidney, the syphilitic character of the disease is highly probable. If in addition to this there is proof of previous syphilitic infection, the diagnosis becomes almost a certainty. Lastly, if antisyphilitic treatment effects a permanent cure—that is to say, not merely a temporary relief such as often occurs in coronary affections from any cause, but a permanent cure of the trouble—the diagnosis of syphilitic heart disease may be considered as absolutely certain. The following case observed several years ago may serve to illustrate this: A young man, merchant, about twenty-eight years old, had been suffering for a number of weeks, as his physician stated, from typical attacks of angina pectoris. He was compelled to remain absolutely quiet because the slightest exertion, even sitting up in bed, produced violent dyspnœa, palpitation, precordial distress, and pains radiating through the chest and arms. The usual routine remedies—strychnine, digitalis, nitroglycerin, morphine, etc., etc., had all been given without result. I found the young man in a pitiful condition; his lips were pale and somewhat cyanotic; the slightest exertion, such as turning in bed or even speaking in a loud voice, produced dyspnœa and the characteristic cardiac cough. The pulse was extremely weak, thready, accelerated and irregular as to rate and volume. The apex beat was diffuse and dislocated toward the left; the heart dulness extended from about the middle of the sternum to somewhat beyond the left mammillary line. There were no genuine heart murmurs, but the first sound at the apex was rough and impure; at the base, faint and muffled. The second aortic and, in a slighter degree, the second pulmonary were distinctly accentuated. The lungs were normal with the exception of scattered râles of varying character here and there. All other organs apparently normal. There was a clear history of syphilitic infection several years ago which had been treated for only a short time. The scar on the penis was still visible and enlarged inguinal glands were present, but no signs of an active syphilitic process were found. There were no evidences of arteriosclerosis, but on the contrary, the arteries appeared everywhere soft and entirely in accordance with the age of the patient. The urine was of normal specific gravity and contained neither albumin nor casts. The temperature was normal. The account of the attending physician as well as of the patient himself and his attendants, left no doubt as to the paroxysms, which occurred most frequently at night, being attacks of genuine angina pectoris. It was clearly a case of disease of the coronary arteries, together with myocarditis, dilatation, and incipient insufficiency of the heart. In view of the age of the patient, the absence of other etiological factors, the ineffectiveness of the usual therapeutic measures and the assured history of syphilitic infection, we were justified in assuming with reasonable certainty that we had to deal with a syphilitic process involving the coronaries and the myocardium. A rigorous course of antisyphilitic treatment, consisting of mercurial inunctions and rapidly increasing doses of iodide of potassium, was at once instituted. Digitalis was still administered for a few days but was soon dropped and the treatment carried out on antisyphilitic lines only. A rapid and steadily progressing improvement of all symptoms followed. When I saw the patient again after about two weeks, the attacks of angina pectoris had entirely ceased and he was able to be out of bed without dyspnœa or other unpleasant subjective symptoms. The dilatation of the heart had very materially decreased, but the heart boundaries as shown by percussion were still not quite normal. The pulse was much slower and stronger but still slightly irregular. The systolic sound at the mitral was clear; the second sound at the base still somewhat accentuated. The same line of treatment was continued. About two years later I had occasion to see the young man again. He had in the meanwhile, it appears, been perfectly well and able to do his work and live his usual life without any inconvenience. A very careful examination showed entirely normal conditions of the heart as well as of the other organs. A number of similar instances might be cited, but this one case is quite sufficient to emphasize the essential features of the clinical picture. The rapid and complete effect of the antisyphilitic treatment in this case was doubtless due to the comparatively recent development of the process; the lesions in the coronaries and myocardium were presumably still mainly cellular, and as such, capable of complete absorption. If the process had advanced to the formation of connective tissue or of fibrous or cicatricial induration, it might perhaps have been possible to combat the attacks of angina and to restore to the heart a portion of its normal tone and vigor, but a certain amount of myodegeneration with more or less pronounced cardiac insufficiency would undoubtedly have persisted and the heart would never have recovered practically normal conditions.

From all these considerations and from the anatomical facts outlined above, an opinion may be formed as to the diagnostic value to be accorded to the effects of antisyphilitic treatment in cardiac affections. The ex-juvantibus diagnosis is nowhere so firmly established as in the domain of syphilis. Does it hold good in heart disease? The answer to this question should, we think, be as follows: Whenever antisyphilitic treatment results in complete and permanent cure, the conclusion is justified that

the disease is of syphilitic origin. On the other hand, an incomplete cure of the lesions and symptoms, or even the entire failure of the treatment to influence the pathological conditions does not necessarily exclude syphilis as the primary cause of the disease.

A somewhat different picture is presented by another and quite large group of cases in which we find some organic heart lesions: myocarditis, pericarditis, murmurs, possibly with all the signs of valvular disease, angina pectoris of the aged, associated perhaps with pronounced general arteriosclerosis or with other degenerative processes—all of them lesions which, neither in their development nor in their subsequent course suggest any reason for suspecting syphilis. At the same time, however, the appearance of syphilitic foci, be they recent or not, in other organs, as the liver, the brain, etc., would seem to point to the possibility of the heart lesions also being syphilitic in their origin. In such cases very favorable results are often obtained by vigorous antisyphilitic treatment. An absolute cure is, of course, hardly to be expected, but improvement, sometimes to a very astonishing degree even in cases apparently desperate, is not at all infrequent. I will not stop to cite illustrative cases. I have had occasion to observe quite a number of cases of this type myself and numerous others may be found in the literature (Gerhard, Curschmann, Semmola, Saccharjin, Mracek, Lang, and others). For a complete and exhaustive account of the literature of the subject up to 1893 the reader is referred to Mracek's excellent monograph (*Archiv für Dermatologie und Syphilis*, Supplement, 1893).

All that has just been said of heart disease of adults and those advanced in years applies also to children and infants infected with congenital syphilis.

There is another and very large group of cases in which any suggestion or indication of syphilis is absolutely lacking; if any luetic infection can at all be made out, it occurred long ago and has been superseded by many years of absolute freedom from any specific symptoms. The primary infection has, perhaps, been forgotten, was never recognized, or is deceitfully denied—in short, though there may not be the slightest reason either from the history or from the clinical symptoms to suspect syphilis, the specific virus is nevertheless active in the heart and proper treatment may effect surprisingly good results.

As a summary result of the preceding facts and reflections the following statements may be made: Cardiac syphilis is not a rare, but, on the contrary, rather a common disease. It is often possible to make a diagnosis of heart syphilis with exactness and certainty; more frequently, however, the diagnosis, while not absolute, is one of greater or less probability. However, that may be, it is incumbent upon us to take syphilis into consideration as a possible factor in *every* case of heart disease, and it should be steadily borne in mind that even in infants, as well as in subjects far advanced in years, syphilis *may* be an important element in the case. I do not wish to be understood to mean that every child suffering with acute rheumatic endocarditis should be dosed with iodide of potassium, and that every old man or woman tottering slowly to the grave with arteriosclerotic degeneration should have their few remaining months made miserable with mercurial inunctions and injections; but even in these cases it should be perfectly clear to us why the question of syphilis is to be excluded. Our attitude toward many cases of heart disease should be similar to that commonly taken toward certain affections as tumors, etc., of the central nervous system. Let the patient have the benefit of the doubt and let an attempt be made with specific treatment even if the syphilitic nature of the disease is neither clear nor even probable. This standpoint which I have advocated for many years has been recently gaining ground. Krehl ("Krankheiten des Herz Muskels," Nothnagel's Cyclopedia) takes the same stand and points out that careful treatment with iodides and with mercury can do no harm, but, on the contrary, may often prove useful even in such cases as are not syphilitic. O. Rosenbach's dread of large doses of iodids in heart disease will generally be considered exaggerated and unnecessary. The irritation of the vascular endothelium, which he particularly fears, is by no means proven. On the other hand, it may be noted that very large doses of iodid of potassium are not at all necessary. In the majority of cases very moderate doses will be sufficient provided that they are given for a sufficiently long time and are supported by mercury, best employed in the form of inunctions or hypodermic injections. Where the stomach will not bear the drug it may still be administered by the rectum or iodipin may be employed to advantage.

In conclusion let me say that, just as, according to our conviction, syphilis as a possible factor should be considered in every case of heart disease, so on the other hand, a possible heart disease should be considered in every case of syphilis. In every case of syphilitic infection the heart should be an object of constant and most careful observation. Most syphilitic heart lesions remain latent for a very long time without giving rise to any subjective symptoms, or these latter are so very slight as easily to escape the attention of the patient as well as of the physician. Often, however, very serious cardiac disturbance, apparently quite acute and without premonition, or a surprisingly sudden and entirely unexpected death of heart failure, testifies to the fact that pathological changes must have been going on in such hearts for a long time unnoticed and unsuspected. It must be borne in mind that the pathological changes must be considerably advanced before they cause subjective or clinically perceptible disturbance. Furthermore, the likelihood of effecting a complete restoration to normal anatomical and functional conditions is the greater the earlier the process is arrested, the less tissue changes have taken place, the sooner energetic and adequate treatment is instituted. Another point to be remembered is that one must not look for very pronounced physical signs—murmurs, dilatations, endo- or pericarditic symptoms are not to be expected in these early stages. Slight arrhythmia, an occasional dropping of beats, roughened or diffuse systolic sounds, accentuation or reduplication of the second aortic or pulmonary sounds are in these cases of grave significance and merit the earnest attention of the physician. At every examination of the syphilitic patient the closest attention should be paid to the condition and function of the heart and he should be discharged from treatment only when there is assurance not only that all palpable signs of syphilis have been removed, but also that the heart is, as far as possible, in its normal condition.

22 East Sixty-second Street.

Dr. Samuel M. Brickner, who has been associated with the Gynecological Department of the Mount Sinai Dispensary, has been appointed Adjunct Gynecologist to the Mount Sinai Hospital. Dr. Brickner's active service begins with the opening of the new hospital buildings, in March.

HIGH-FREQUENCY CURRENTS IN THE TREATMENT OF SKIN DISEASES.*

By CHARLES W. ALLEN, M.D.,
NEW YORK.

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; CONSULTING DERMATOLOGIST TO THE CITY AND OTHER HOSPITALS.

It must be conceded that we are passing into the dawn of a day of physical methods in medicine. Not only does the physician of 1904 give fewer and less drugs than his brother of 1804, but the patient is, I believe, less inclined than formerly to take large and frequent doses of physic. Whether or not this is altogether as it should be, will probably be better known to the practitioner of 2004. Being neither an electrician nor an electrotherapist, still as a dermatologist I have found myself drawn into the employment of a variety of physical methods during the past few years, several of which have to do largely with electrical currents.

Desirable as it is that every physician should have a knowledge of physics, still I maintain that a practitioner in any department of our science may acquire sufficient knowledge and skill in the successful employment of these useful measures without becoming thoroughly schooled in electricity, just as he becomes most successful in administering drugs without possessing all the knowledge that the pharmaceutist is forced to acquire.

I shall therefore attempt to discuss the nature of high-frequency currents, rather from their practical bearings, than from the side of strict electrical science, endeavoring to state the case in such a way that one wholly unfamiliar with the subject may gain some idea of what these newly recognized forces are and how they operate. In attempting to do this, which I realize is no easy task, I shall try to answer the questions: (1) What are high-frequency currents? (2) How are they produced? (3) How are they applied? (4) How is their action accomplished? (5) Of what value are they in dermatotherapy?

In approaching this whole subject it is well for us to make a distinction from a historical consideration, between high-frequency currents and treatment by them.

The first must be claimed as essentially of American origin. The second belongs to France by right of perfection of means and popularization of methods. Morton, in giving us his static induced current which was a newly recognized form of current in 1881, became one of the pioneers. His current, however, must not be considered according to some authorities as one of high frequency, being a unidirectional interrupted, and not an oscillatory current. His discovery was preceded in 1842, by that of Joseph Henry, also an American, who showed that the discharge from a Leyden jar was oscillatory and not continuous, as had been thought.

Tesla, likewise in this country, ten years after Morton, in 1891, by an ingenius arrangement of step-up transformers, multiple-pole alternators, and other devices, produced currents whose potential entered into the tens and even hundreds of thousands of volts.

The employment of high-frequency currents in medical practice did not attract much attention until d'Arsonval, in 1890, devised an alternator capable of ten thousand alternations per second.

From this time forward currents of high voltage and great frequency became more and more employed in France in the treatment of disease and attracted much more attention for a number of years upon the other side of the Atlantic than here.

*Address delivered by invitation at the annual meeting of the West Side Medical Society.

While French literature is somewhat extensive, comprising some twenty papers by d'Arsonval, a dozen by Oudin, and many by such able men as Apostoli, Bordier, Denoyés (including a volume of 365 pages), and my friends Brocq, Gastou, Bisserié, and others, comparatively little has appeared in our own journals. It may be said, I believe, that until Dr. William's little volume was published last year in London, no adequate chapter on the subject had appeared in the English language. To those of you who have not read it I would call attention to the excellent paper of my friend Dr. Piffard in the MEDICAL RECORD of October 31, 1903.

What Are High-frequency Currents? It is well known that if a condenser, such as a Leyden jar, be so arranged that its internal and external armatures are connected by a good conductor, forming an arc, the internal terminating in a metallic ball—and that if we excite in the conducting wires a gradually increasing difference in potential, a time will arrive when the condenser will discharge upon itself.

In order to keep up this discharge we must introduce into the condenser, its original electric charge at intervals of the smallest fraction of a second. No mechanical interruptor hitherto devised could supply this requirement.

It was only when the electric spark was introduced for this purpose that high-frequency currents became a possibility. The discharge between the terminals of the condenser will be oscillatory and of enormous frequency when the proper difference of potential is reached, and we have a continuous oscillating discharge.

The currents originate in the external armatures of the condensers when stimulated by an efficient source of electricity. They have such a high voltage that air, which is usually considered an excellent insulator, ceases to operate as a non-conductor so that the currents may be conveyed to the patient without the intervention of the usual conducting wires.

The current passes through a coil of wire in the form of a helix, known as a solenoid, when an electric discharge jumps from one of the internal armatures of the condenser to its fellow. The designation high frequency is almost confined in Europe to currents derived from apparatus designed by d'Arsonval and Oudin or modifications introduced by others.

There are a number of high-frequency currents, differing somewhat from one another, at times differing materially in character. In this country a form of high-frequency current has, of late years, become familiar as the hyperstatic. This was worked out and named by Piffard, basing his investigations on those of the European investigators mentioned.

This apparatus, used in connection with the static machine, furnishes a current by induction of high potential as compared with that of d'Arsonval, which is comparatively a low potential current, the patient being in a circuit by auto- or self-induction in both cases.

It is, then, in the indirect or alternating form of electricity that these currents originate, and as this has to do with low amperage as compared with direct or continuous currents great voltage or force of current can be made to enter the body without danger, when properly transformed, and with comparatively high amperage, because of the alternating character.

How High-frequency Currents Are Produced.—High-frequency currents may be produced by the aid of any electrical plant capable of generating *x*-rays. If a coil be used, the two poles of the secondary may be connected with the internal armature of one or two condensers arranged with bulb dischargers.

The size of the bulb has a bearing upon the rapidity of discharge and potential or force of each discharge; the larger the bulb the more forcible but the slower the discharge. The external armatures of the condensers are connected by a solenoid of low resistance.

The patient to be operated upon is connected to one or two points of the solenoid, which latter acts as an impedance; the patient being in shunt or derivation to it. The object of this is to avoid placing the patient in direct circuit with the condensers, as the too great impedance would prevent the extremely frequent oscillations necessary to the production of this variety of current as a method of treatment. If the connections are made with a static machine, a current is produced having higher voltage and lower amperage than when a coil is used.

Apparatus.—To Tesla is due the credit of devising the first apparatus making possible, through subsequent improvements, the production of these currents as they exist to-day. Tesla's device consisted in a coil the insulation of which was supplied by oil, instead of air, making possible the necessary protection against leakage which enabled high-tension apparatus to be subsequently perfected. His apparatus was in reality a transformer, utilizing the secondary current from an ordinary induction coil and transforming it into a current of even higher potential, and constituted what is known as a step-up transformer.

D'Arsonval's apparatus consisted of an induction coil, a helix of thick wire immersed in oil as an insulator, and condensing jars. He has also suggested for currents of great power to use instead of the Ruhmkorff coil another transformer with closed magnetic circuit energized by an alternating current. The internal armatures of the jars are connected with the source of high potential, and the external to the extremities of the solenoid, the patient being connected between any number of the loops desired.

The current is one of comparatively low voltage, and as such is to be distinguished from the resonator current and the hyperstatic current, which are generated in connection with a solenoid of fine wire, the current being obtained in the Oudin apparatus, which we will next consider, by resonance, and in the Piffard apparatus by induction.

In a modification of the d'Arsonval apparatus, introduced by Gaiffe of Paris, an oil condenser is used instead of Leyden jars.

D'Arsonval's bipolar coil, or resonator, consists of a cylinder of wood about which is wound some fifty yards of fine wire. Surrounding this, but at a distance from it, insulated by the air are four loops of much thicker wire, connected to a sliding base so that the outer set of loops can be placed as desired opposite any portion of the cylinder; the advantages being that fine gradation of effect may be obtained, or the cylinder may be made to use as a resonator, starting from either extremity at which the outer loops are placed.

The Oudin resonator consists of an upright cylinder, taking the place of the horizontal one just mentioned, the winding of fine wire being the same.

About the base is a stationary solenoid, consisting of larger wire, wound helically with few turns. The upper cylinder is not traversed directly by the current, but is thrown into vibration in resonance with that of the lower larger wire at the base, through which the oscillating current is made to pass by suitable connection.

Attached to the large wire helix is a movable contact, by changing whose position on the loops the two resonators are, so to speak, attuned to each other and to the rate of interruption in the primary. The function of the fine-wire cylinder is to amplify the current passing. This has its counterpart in music in the well-known harmonious vibration of the tuning fork and the amplification of the tone of the church organ secured by the cylindrical pipes.

The explanation of the phenomenon is somewhat clearer if we remember how a taut string of a violin, for example, vibrates with greater rapidity at the extremity remote from the part to which the impetus is applied.

In connecting up a resonator, one or two condensers, as the case may be, being connected in the circuit, a flexible wire joins a coil of the solenoid to the coils of the resonator. The other end of the solenoid may be grounded.

The Piffard apparatus, which I have employed during the past three years, is a transformer consisting of two Leyden jars as condensers. The wooden case encloses a helix of thick wire, surrounding a coil of fine wire, the insulation between the two being of glass and air, instead of oil or paraffine, as in some other makes of apparatus.

Originally the spark attachment consisted of a sliding metallic bar playing within a glass tube, which tended to muffle the sound of the spark. This contrivance was soon found to impair the working efficiency, and has been replaced in my own apparatus by an inch only of the metal bar projecting on either side, to serve as a safety spark-gap whenever the sliding bars of the static machine itself become too widely separated, so that the resistance of the spark-gap on the static becomes greater than the resistance between these two points on the hyperstatic and thus endangers the apparatus. The strength of current employed is regulated entirely by the sliding-bar of the machine; one inch separation of the poles being usually sufficient.

The apparatus has been further modified of late by the introduction of binding posts connected with the terminals of the primary coil.

Electrodes attached to these posts enable one to give a mild form of d'Arsonvalization without interfering with the use of the original hyperstatic current which may be coincidently applied to the body's surface. In the matter of electrodes, there are a great variety, in shape, form, make, and material. An efficient metal electrode for a feathery discharge consists of metallic points projecting from a flat base and surrounded by an insulating ring.

Glass vacuum electrodes are among those most frequently employed in this country, where they were first introduced, and are constructed in many designs for application to the various accessible cavities of the body. I am not prepared to state whether the gases contained within these hollow electrodes, or their high or low degree of vacuum, modifies, to any great extent, the treatment.

My ignorance of the subject is not a matter of surprise, since Geisler, the inventor of vacuum tubes, did not pretend to know anything about the action, and Lord Kelvin, who has devoted a volume to the consideration of the passage of electricity through gases in vacuo, propounds five hypotheses, none of which satisfactorily explains the question. My belief is, however, that the presence of actinic rays in the spark may exert a beneficial effect in some conditions, and this view is held by some of the gentlemen with whom I spoke on a recent visit to Paris.

How High-frequency Currents Are Applied.—There are a variety of methods of application, based upon the physical properties of the current. The commonest are by what are termed autocondensation, general electrification, local application by contact, and autoconduction.

1. *Autocondensation* is secured through a general electrification by placing the patient on a couch fitted with metallic connections rigged up with conducting wires, one passing from the metallic portion of the couch and the other from the patient through a handle to the two extremities of the solenoid.

2. *General electrification* is secured by monopolar effluvia or feathery discharges which go off in great abundance from the electrode, the patient not of necessity being in contact with another electrode, couch, or body-solenoid.

3. *Locally*, by means of glass, carbon, or metallic electrodes brought into immediate contact with the body. This can be bipolar, if stronger effect is desired, and in d'Arsonvalization. The d'Arsonval current and general electrification or direct contact through an electrode may be coincidently administered.

4. *Autoconduction* is the term applied when the patient sits with the feet in a water bath, to which one pole is connected or is enclosed, without contact, in a large solenoid, forming a cage which is connected with the resonator or high-frequency apparatus. The cage-solenoid may be made to act as a resonator; the patient being internally instead of externally situated in reference to the latter.

It differs from other modes of administration by the fact that there is no direct contact connection between the patient and the current, but is in an oscillating magnetic field which permeates his body. The patient can be coincidently placed in monopolar derivation to the solenoid by grasping a hand electrode from one pole of the solenoid.

How the Action of High-frequency Currents Is Accomplished.—What is claimed for these currents and what effect can be actually produced, do not always amount to the same thing. There is a greater scientific employment of electricity at the present day, probably, than ever before in the world's history, and still never has the medical profession been face to face with more outright faking than in recent times. We have, beyond a doubt, in these currents a method of stimulating vital energy hitherto unknown; a physiological and chemical tissue-change has been shown experimentally, which puts the matter beyond question. Locally, as well as generally, nutrition is improved; it is a tonic to the skin in lowered conditions of this organ, just as it is a tonic to the system at large when given in a way to affect the whole organism. Its anæsthetic properties can be utilized in a local way, and the effect of local anæsthetics as well as dehæmatizing agents can be somewhat increased by its local application.

The beautiful play of color within the electrode, the brilliancy and fascinating aspect of the spark as it jumps to the covered or uncovered body of the patient, have all the elements necessary for successful suggestion, and no doubt this effect plays no small rôle, especially in certain classes of susceptible patients. Given in a darkened room, the electrical effects are most beautiful and impressing, simulating in miniature, natural phenomena, ranging from the aurora borealis of the Northern sky through the flight of meteors and showers of stars to the electrical storm with its forked and chain lightning and atmospheric ozonization; the detonation of the primary discharges supplying the thunder.

The chief physiological claim made is that the currents increase metabolism, and that nutrition processes are improved; tissue changes being accelerated, the system is better able to throw off pathological processes and to resist microbic and other noxious invasion.

Powerful effects are made possible by the introduction of foot, or hand baths, the condensation chair or the large cage solenoid.

It is claimed that arterial pressure may be raised, and that by increasing oxidation and elimination decided effects may be produced upon systemic affections of grave nature, malignant disease, anæmic states, neurasthenia, chronic rheumatism and gout, obesity, diabetes, phthisis, etc.

Among general conditions which receive prompt relief are pelvic pains due to nerve involvement, postoperative pain, slight paralysis, paræsthesias, abnormal nerve sensations, pruritus, formication, etc. It is contraindicated in acute inflammations, including acute rheumatism, and febrile states, but where there is congestion and infiltration of tissue it often acts with decided benefit.

Effects in Skin Diseases.—Coming now to the subject proper of our remarks, I will premise that during the past few years I have employed these currents of high potential in my office-practice and have applied them to a somewhat wide range of dermotological conditions. I will leave out of consideration the effects claimed for the method in cancer and lupus—although I have convinced myself that as an adjuvant to the *x*-ray, for example, it is at times of decided benefit. I have destroyed very small sarcomatous infiltrations with the high-frequency spark and have given great comfort to several subjects of sarcoma of the jaw by means of the vacuum electrode effluvia and direct contact massage. I have thought also to have observed general improvement from the autocondensation or the d'Arsonval method in severe cancerous as well as other conditions. The chief benefit to be observed from these currents in dermatology, as far as I can now judge, is in those cases accompanied by marked pruritus, pain of neuralgic character, and in the various paræsthesias. In chronic eczemas, I have found the contact vacuum electrode of decided value in alleviating symptoms, and in diminishing infiltration. In lichen planus not only are the lesions improved at times, as I have observed in several cases, but the element of itching is alleviated and general benefit secured. In zoster of the thigh and arm with hyperæsthesia and neuralgic pain, not only has temporary relief been afforded immediately after each application, but the whole course of the disease has been shortened, and the lesions have healed more promptly than without their use.

In looking over my case books I have unearthed 175 histories in which record has been made of the use of these currents. This forms, however, but a part of those treated, as scarcely a day has passed that I have not made use of the method since November, 1901. The cases recorded include 37 of acne, 26 of alopecia, 27 of eczema, 8 of pruritus ani, 8 of pruritus vulvæ, 2 of generalized pruritus, 5 of pityriasis rosea, 3 of urticaria, 4 of lichen planus, 1 of mycosis fungoides, 3 of zoster, 3 of rosacea, 2 of pruritus hiemalis, 1 of pruritus scroti, and scattered cases of psoriasis, chloasma, ichthyosis, keratosis pilaris et follicularis, warty growths, moles, erythema nodosum, generalized molluscum contagiosum, scabies, dermatitis, dermatalgia, ulcers, etc.

European observers, including Freund, Barthélemy, Jacquot, as well as some already mentioned, report excellent results obtained in eczema, psoriasis, impetigo, lupus, alopecia areata, epithelioma, atrophia cutis, pityriasis versicolor, pigment abnormalities, etc.

In Brocq's service at the Broca Hospital, Jacquot reports fifty-six cases of lupus erythematosus with thirty-nine cures; of these, nine were of the fixed and thirty-one of the aberrant or wandering variety—of the latter there were twenty-five cures.

It would seem from this report that the method for the aberrant form is superior to both photo- and radiotherapy. Leredde and Pautrier regard high frequency as the method of choice, and it surely is the easiest and safest for both patient and operator. In the fixed or stationary form, the conditions approximate more those of lupus vulgaris and here coincident applications of vigo plaster, salicylic dressings, deeply acting chemicals, scarifications, electrocautery, radio- and phototherapy are to be energetic ally carried out.

The vasomotor effects may be well studied in urticaria. Here sparking the wheal produced entire disappearance of the lesion, which is replaced within a few moments by a dehæmatized area. Within a few minutes redness returns, which exceeds the bounds of the wheal whose borders are lost in the diffuse erythema.

The effect of contraction followed by dilatation of the vessels is very marked. A feathery discharge over the whole body has a soothing effect, relieving the itching for a time, and appears to shorten the course, though the usual internal measures are not to be neglected.

In the succeeding outbreak I have noted that while some of the wheals returned upon the original sites, those previously sparked failed to reappear, a slight reddened staining of the skin marking their situation. In these regions there was entire absence of itching as well as of renewed eruption. General effluviation with metallic pointed electrode, giving what I call a "feather duster" brush seems to di minish the pruritus, to shorten the individual attack and decrease the entire course in subacute or persistently recurring urticaria.

In conclusion, I can state that high-frequency currents are of decided advantage to those treating skin diseases, but are especially to be employed in connection with other measures. They are curative of themselves in a restricted class of cases.

They aid in relieving symptoms in a larger class, viz., those attended with pruritus. As a whole, high-frequency currents are inferior to the *x*-ray in skin work, but the two go well together.

30 East Thirty-third Street.

THE MEDICOLEGAL ASPECT OF ACCIDENTS CAUSED BY THE RÖNTGEN RAYS.*

By CARL BECK, M.D.,
NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON TO ST. MARK'S HOSPITAL.

In the paper I read before this society at the November meeting of last year I asked the question whether the physician is responsible for Röntgen ray burns on his patients. My expectation was that some of the learned members of this body would answer it, but the fact that my question remained unanswered seems to illustrate its delicacy; and if I venture to approach the subject again, I do it because great strides have been made in the understanding of this most important subject.

That it is most important will not be denied any longer. Fortunately, the day has passed when those few, who took every opportunity to fight for the new method, were ridiculed or at least called erring enthusiasts. When Röntgen illustrations were shown in medical societies the expressions of pity for the utopian views of the speakers were clearly perceptible on the hearers' faces, and the ugly term "moonshine" indicated the key-note of the most frequent criticism.

*Read before the Society of Medical Jurisprudence, New York.

How important the Röntgen rays are in accidents I will illustrate by only a few cases:

One concerns a boy of nine years who sustained a fracture of the elbow, the nature of which was not elicited on account of the swelling. Six weeks later when it was impossible to extend the arm, the Röntgen rays demonstrated the presence of a fragment, broken from the external condyle and turned around so that it was driven into the tissues like a wedge. Its removal by chisel was easy. It was done a week ago and the boy's arm will be perfectly normal.

The other case shows, as I might say, the course of evil, inasmuch as the patient sustained a fracture of the patella twenty years ago, the failure of union rendering his walking uncertain. This uncertainty doubtless caused the subsequent four fractures, viz., Fifteen years ago the fracture of the one wrist, then that of the other; this summer he fell down into a cellar, fracturing his humerus and two weeks ago he selected two ribs as the scene of his fracturing activity. If the Röntgen rays had been discovered twenty years ago, his surgeon would have been able to obtain a better result, and the subsequent fractures would probably not have taken place.

I also wish to show you a skiagraph of a boy of twelve years which I took two days ago, and which illustrates that the sprain he was thought to have suffered from two weeks ago, in reality was a fracture, You can see how the lower fragment slipped upward, taking the whole hand with it, thus crippling the whole extremity. The information obtained enabled me to press the fragment down forcibly, a procedure which I would not have had the courage to undertake before the Röntgen era.

In view of such immense advantages, it appears strange that the general introduction of the method took so long a time. The high price of the apparatus, the many misinterpretations of the Röntgen ray plates, caused by insufficient anatomical knowledge as well as by technical shortcomings and the pretensions of charlatans, are partially responsible for the somewhat slow acceptance of the treatment But one of the most serious objections seems to be the report of burns received through the rays While they were greatly exaggerated by officious friends, confrères, and shyster lawyers, there can be no doubt that burns occur even under the supervision of skilful physicians.

This deplorable experience is explained by the fact that for a long time the peculiar effects and influence of the rays on the human integument were not known. Consequently the rays were applied with little restriction. The questions of dosage and time of exposure were neglected by the same physicians, who know that the same preparation of morphine which may restore health to the sick in small quantities brings death in a large dose. They did not hesitate to apply the new agency, almost without limitation, to their patients. Were they to blame as long as none of us knew better? Some good usually comes out of evil; and the accidents which resulted from this *modus operandi* have enabled us to study the irritating effects of the Röntgen light so thoroughly that we have obtained valuable hints for indications and limitations of its employment in practice.

It was found that the pathological changes of the skin, called Röntgen ray dermatitis and generally known as *x*-ray burns, resemble those in ordinary burns. Just as in ordinary burns, three different degrees should be distinguished.

The first degree is characterized by the symptom of hyperæmia. Epidermis and cutis are infiltrated

and the temperature is somewhat higher. Exfoliation takes place in small scales. The most pronounced subjective symptoms is a tormenting itching in the skin. Effluvium capillorum, which manifests itself, as a rule, without producing any visible signs in the integument, belongs in the same category. It seems that there is a regressive metamorphosis (atrophy) of the differentiated elements, viz., the glands, hairs, and nails. Most cases of Röntgen-ray dermatitis belong in this category.

The first symptom used to be the turgescence of the skin, which may appear as early as three days after the exposure. In the majority of cases, however, unmistakable signs do not show before the tenth day.

The main feature of the second degree consists in the formation of blisters, the clear or yellowish contents of which lift the corneal from the mucous stratum of the rete Malpighi. The inflammatory signs are well pronounced, the tension is considerable and the pain is intense. After the removal of the blisters, the corium is exposed as a red and sore surface (bullous form of Röntgen-ray dermatitis). The excoriated surface shows a yellowish-red appearance. Some cases look like having been varnished. In the further course some portions show a fibrinous cover like croup-membranes, which adhere tightly. The abundant secretion from the coarse granulations is of a seropurulent character.

The third and gravest degree is characterized by the escharotic destruction of the irradiated tissues. They show the signs of dry gangrene, and their appearance is brownish-black. There are intense inflammatory signs and the temperature rises accordingly. The patient suffers considerably. If the necrotic area exfoliates by a slow suppurating process, or if it, as it should properly be, is removed by the surgeon, a granulating ulcer remains, the cicatrization of which may take months (necrotic form of Röntgen-ray dermatitis).

Then the integument becomes hyperæmic, erythema of a light red appearance develops and changes in the pigmentation set in. If the irradiation is continued in this stage, these signs, especially erythema and pigmentation, disappear in two or three days. The integumental turgescence lasts somewhat longer. After depilation, the first signs of the recurrence of the hair show in five to nine weeks. In a few weeks there is complete recovery, though sometimes slight pigmentation of the integument remains.

If the irradiation is continued, the skin may become burned and scaly; or the bullous type of Röntgen-ray dermatitis set in. In this form intense reaction takes place after an incubation of about two weeks. This is of a subjective as well as of an objective character, and lasts about as long as the period of incubation did. Then cicatrization takes place. If the area of irradiation was covered with hairs, depilation is observed. The process of regeneration of hair is slow, and pigmentation and teleangiectasis nearly always remain.

The necrotic state of the Röntgen-ray dermatitis develops a few days later than the bullous form, as a rule, and requires months for its cure. This type reminds one of the stationary form of gangrene, which is known as "glacier-gangrene" in Europe. The antediluvian face of the old inspector of the ice-grotto at the Eiger glacier in Switzerland, well known to many medical tourists, affords a real study of this interesting tissue change.

There is a type of chronic Röntgen-light dermatitis which is especially found among physicians who devote a great deal of time to irradiation. This is illustrated by a photograph of the wrinkled, shriveled, vulnerable, and partially cracked terra-cotta hand of a physician, who had done daily skiagraphic work since the early Röntgen era. The condition is seen on the dorsal surface, which he turned against the Röntgen tube in order to ascertain, by the study of the bones of his own hand, what degree of translucency existed. The tip of the fourth finger was the most exposed target, which finds its conspicuous expression in the black colorization of the nail and the onychia. Next to it the little finger suffered most which is illustrated by the deep black of its nail. The nail of the middle finger is less blackened, and the index still less, while that of the thumb, which is held sidewardly, is fairly normal.

The hands of Röntgo-active physicians show the integument wrinkled and shriveled; the nails horny and cracked and the phalanges thickened, so that there is tension during movement. The elasticity is lessened and the sensibility increased. Effluvium capillorum is an invariable accompaniment. In some cases the formation of warts and rhagades is observed. Undoubtedly there is a cumulative influence.

Experience has taught us that in all cases of Röntgen-light dermatitis, other circumstances being equal, long exposures had taken place; and it is therefore obvious that short exposures are the best safeguard against the injury; but then the question is, Shall we reach the desired result, whether for diagnosis or therapy, by a short exposure? If not, what kind of prophylaxis must be used?

In order to appreciate this important point thoroughly, we must also consider some contributing factors, viz., the construction of the tube, the penetration power of its light, the distance from the irradiated body, the position of the object, the number of interruptions and the size of the secondary.

Whether an accumulator, a static machine, or a coil be used, seems to be irrelevant. But, as mentioned in previous publications on this subject, we have to reckon with Röntgen-light susceptibility, existing in some individuals, just as we have to do with iodoform idiosyncrasy. My statistics at the German Poliklinik of New York, which are based upon twenty years of continuous observation, show that about every fiftieth individual becomes affected with dermatitis when treated with iodoform. Since such idiosyncrasy cannot be diagnosticated before the dermatitis makes its appearance, we shall never be able to prevent it. But what we can do is to recognize it in its early stage, and if this is done, further spreading can be arrested by simply discarding its further use.

There are, however, two points of difference between the iodoform idiosyncrasy and the Röntgen light susceptibility. In the first place, a non-susceptible patient will not show any signs of iodoform dermatitis, no matter how long he may iodoformize himself, while there is no individual who would not be burned by the Röntgen light if its influence is kept up long enough. And, secondly, the Röntgen dermatitis will not stop as soon as further irradiation is discontinued. The peculiar features of the Röntgen rays, not to show the injurious effects as a rule before the tenth, sometimes not before the twentieth, day after the first exposure, stands in the way of an early and rational prophylactic therapy. The only method by which we may so far determine whether susceptibility exists or not is by tentative exposures. So it may sometimes be a chain of little causes: long exposures, short distances, powerful apparatus, condition of patient and weather, which in their entirety may be the stimulus for the reaction. Beside this inclination, which is borne with the individual and is to be regarded as an imponderabilitum, temporary

susceptibility exists, which may be attributed to temporary bodily conditions, to pathological changes or to climatic influence. I have repeatedly called attention to the observation that when suffering from a slight Röntgen light dermatitis myself, I could note a marked increase of the symptoms during sultry weather. The patients treated on such days had a similar experience.

I do not, however, believe that the question of susceptibility requires much consideration as far as exposures for diagnostic purpose are concerned, since with our present methods, the length of time needed is very much shorter. Even if repeated exposures have to be taken, so far I did not see a Röntgen-light dermatitis before the fifth repetition, the intervals having been from two to three days. And these cases were slight, the first or second degree. Still, as already said, with our present apparatus, a certain length of exposure invariably causes burning, whether the individual be susceptible or not. If long exposures are responsible in nearly all cases of Röntgen-light dermatitis, we shall naturally try to shorten them, as emphasized above. This we can do only to a certain extent, if we are seeking full and distinct diagnostic information. Unfortunately, the best skiagraphs are obtained by long exposures, made with tubes of low vacuum. This, in addition, requires a strong current. So, in order to get out the structural details, three irritating factors unite their influence, the long exposure, the soft tube, and the intense current. A tube with a high vacuum requires only a short exposure, but the details of the skiagraph are by no means brought out as well. So, theoretically, if the question of dermatitis did not exist, we would, as a rule, combine very low vacua, very long exposure, and currents of high intensity.

Fortunately, the longest exposure (the pelvis) does not now, with the aid of the Wehnelt interrupter, require more than about five minutes' exposure, and this will be tolerated even by a susceptible individual. So, practically, we do not need to fear much in our diagnostic efforts, and if we could make the rays still more powerful, in order to get more differentiation, we would not hesitate to do it.

But when repeated exposures of ten minutes' time are necessary, the question of susceptibility, as well as of ordinary cumulative irritation, should be considered, and therefore the intervals between the exposures should be made long—a week on an average.

None of the severe disturbances, however, reported in literature were due to short exposures, most of them being observed in professional electricians. A tube-maker in a Hamburg laboratory, for instance, by testing the tubes with his own hands, sustained a burn of the third degree, the treatment of which was apparently neglected. In the deep ulceration formed, over the basis of which an epithelioma and metastasis in the glands developed, so that disarticulation in the shoulder-joint had to be undertaken.

Dr. Samuel Lloyd, who has done me the honor of being present, reported the case of a tube-maker in Edison's laboratory who had received very severe burns on his hands and head. Finally he lost all the skin of his hands. He was skin-grafted in two or three hospitals, and finally returned to New York with an epithelioma developed on the *x*-ray burn of the right hand. This epithelioma grew rapidly, while he was under *x*-ray treatment, and finally amputation had to be performed. (MEDICAL RECORD, April 4, 1903, p. 554).

Tuttle (*ibidem*) referred to a man whose thigh he had to amputate because of the result of an *x*-ray burn. A careful pathological and microscopical study of the *x*-ray burn, as well as of the parts around it, had been made by William Vissman, whose conclusion was that it was the result of the production of an endarteritis and a periarteritis.

As far as I could astertain, extremely long exposures had preceded this injury. The pathological changes in the tissues were studied by Unna, Gilchrist, Kienboeck, Darier, Jutassy, Kibbe, Gassmann, Scholz, Oudin, and others. Unna found a slight increase of the nuclei in the papillary body as well as around the blood-vessels. At the same time there was more pigment in the upper layer of the cutis.

Kibbe found dilatation of the blood-vessels and rich cellular proliferation. Gilchrist noticed abundant brown pigment, in the mucous stratum and dilated vessels in the corium, while the corneal structure was thickened. Darier observed enlargement of the reticular cells, thickening of the epidermis, and atrophy of the hair and its follicles, and of the glands.

Examination of burned tissue made by me (see "The Pathology of the Tissue Change Caused by the Röntgen Rays," and Transactions of the Medical Society of the State of New York, January 28, 1902) showed a large amount of dense connective tissue and marked vascularity. The epithelial cells of the skin were diminished in size. The tunica intima of the small blood-vessels was thickened, their caliber thus becoming narrowed. The muscularis and adventitia appeared to be affected in the same manner. The muscularis may thus become atrophic. All this points to a process of constriction of the vessels. Some of the areas show still greater degeneration, the tunicæ of the small vessels being converted into a colloid mass and the intima being entirely severed from the muscularis.

The hair extracted after prolonged irradiation is found to have lost its structure. It ends in a point instead of showing a root. Zehmann found that the bulb at the end of the root often showed slight swelling.

The course of the Röntgen-light dermatitis is dependent, of course, upon the intensity and extent of the irradiation, and upon the kind of affected tissues. The prognosis of the second and first degrees is extremely favorable. The integumental area, situated directly above the bone, as on the skull, chin, thorax, spinal column, tibia, etc., being especially unfavorably located. The necrotic form naturally represents the severest type.

The more intensely the dermatitis sets in, the more the tissues are affected, and the more the consequences appear. The following case observed by me may serve as an illustration: The bullous form of Röntgen-light dermatitis was observed in this man of thirty-eight years, who, in the course of three years, had to submit to five thoracotomies for pyothorax. In view of the thickened pleura, which lined the immense thoracic cavity, I had resorted to pleurectomy, and a few weeks later the Röntgen rays were expected to give imformation as to the extent of the cavity, as well as of the previous rib-resection.

At first soft tubes were employed, the use of which gave but little contrast. This phenomenon was erroneously explained by the reason that, in spite of the removal of a large pleural portion, still a considerable part of thickened pleura had remained, which might have veiled the image of the ribs. When resecting the ribs shortly after the last exposure found them to be of very soft consistency, which showed the absorption of calcareous matter on account of the long duration of the inflammatory process (inflammatory atrophy). After having re-

peated my unsatisfactory efforts seven times, harder tubes were resorted to in combination with a high current and longer exposure, which caused a bullous dermatitis. The incubation lasted ten days, the skin was light-red first and then dark red. Later on, a blister the size of a large hand formed, the contents of which consisted of serum. After the blister was removed an excoriated surface was exposed, which cicatrized under a xeroform dressing in three weeks. Now, two years after the healing of the dermatitis, the pigmented integument indicates the presence of a telangiectatic area. The patient is of blond complexion.

The peculiar circumstances of the case must justify the repeated exposures, and I do not believe that this patient who suffers from his teleangiectasis has ever thought of holding me responsible for it. But suppose he would, I trust that the bar would sustain me.

In the chronic form I recommend repeated bathing in a decinormal salt solution.

In severer cases it appears to be natural that the patient is only too much inclined to blame his examiner. Whether the operator was negligent or not seems to be immaterial to the great majority of the injured; all they see are the consequences. In the court cases in which I was called upon as an expert, I was shocked by the unjust, if indeed I may not say the felonious, attitude of the plaintiffs. Although with our present means it should not appear very difficult to settle the question whether the physician has committed any negligence or whether he or his patient is the victim of unfortunate circumstances, there is hardly any subject in the wide field of medical jurisprudence where juries, judges, and experts disagree as much as in this field. The decisions of the courts in this country as well as in Germany, England, France, and the Netherlands illustrate a most deplorable state of affairs in this matter. French courts excelled in decisions against physicians, especially in all cases in which the corpus delicti has consisted in injury to the complexions of the fair sex.

Some time ago, in this state, a suit was dismissed which had been brought against a dentist of good repute who had suspected the neuralgia of his patient, a young lady, to be caused by a foreign body in her jaw. The dentist very properly recommended that a Röntgen-ray photograph should be taken in order to verify his suspicion. At that time few physicians were familiar with the technique of the new method, wherefore an electrician was recommended who had the reputation then of being an "*x*-ray specialist." The result after repeated exposures was an extensive burn of the third degree around the neck of the patient. The patient claimed that "a million volts of electricity" were used. Undoubtedly a somewhat excessive voltage, and one which should justify the large amount of damages demanded! The court upheld the defendant's contention, that the patient had voluntarily submitted to the Röntgen-ray exposures upon the advice of the dentist, and, as he had not administered the treatment, he was not liable. The dentist, in fact, deserves high praise in seeking the best information for the cause of his patient's ailment. The question of the responsibility of the electrician is still left open.

In this country several cases are on record in which burns were caused by searching for renal stones, the prolonged examination being done by expert physicians. Only in one case, as far as I know, the patient commenced suit against one of the best experts in Röntgography. The suit was dismissed by the judge.

The suit against Professor Hoffa of Berlin, the famous orthopedist, became widely known not only because of the prominence of the defendant, but more so for the complicated etiology of the injury.

The patient suffered from ankylosis of his hip, presumably after coxitis, for which he was treated by the Röntgen rays under the supervision of an "*x*-ray specialist." Altogether he was exposed six times. No change for the better taking place, the patient consulted Professor Hoffa, who advised a diagnostic exposure in order to ascertain the condition of the hip-joint. The distance of the tube from the abdominal integument was 30 cm., the length of exposure twenty-five minutes. Ten days later extensive dermatitis set in, which induced the patient to bring charges of criminal negligence in the treatment. Professor Hoffa, in defence, claimed that the exposure was made according to the principles adopted by the medical profession, and that furthermore the sensitiveness of the skin was increased by the previous irradiations. The district attorney, after having called upon an expert who sustained Professor Hoffa, dismissed the claim.

Nowadays, by our greatly improved means, Hoffa would not have burned his patient, even in spite of the preceding irritation, because he would not have been exposed for twenty-five minutes. It is only a few months ago that I had an opportunity myself to see Professor Hoffa take a beautiful Röntgen plate of a hip in three minutes.

We may safely expect that damage suits for Röntgen-ray burns, caused during diagnostic exposures, will become very infrequent. But with the employment of the rays for therapeutic purposes this question of injuries has entered into a new phase. Burns have now become a rather common accident. In several instances suits were brought against physicians, especially on the ground that they did not use the necessary means of protection. In most of these instances the severe character of the diseases demanded a severe treatment, so that burning had to be risked. This fact alone is sufficient proof of the perfidious nature of the suits. In cases in which only cosmetic considerations are concerned, such risky therapy is unnecessary.

It is not customary to shoot at sparrows with cannon balls. Why, if we treat a hairy surface on the face of a fair lady, for instance, resort to means as powerful as those we employ in carcinoma? And, on the other hand, if dermatitis occurs in the face of a fair lady, who simply wanted to be treated for hypertrichosis, the cure may prove to be worse than the disease. In other words, when treatment for non-malignant diseases is intended, careful tentative exposures should precede it. If, then, erythema should appear after one short exposure, thus proving the presence of special susceptibility, further treatment must be taken up only under extraordinary circumstances, and after the patient has been fully informed of the risks. For such purposes a first exposure of five minutes is advised. A soft tube should be selected. After a week the same procedure, now lasting ten minutes, is to be repeated. If, after a third exposure, and two weeks after the first one, no reaction has shown up, the patient is apparently not specially susceptible. Then he may, on an average, be irradiated every second or third day, and at last daily, until reaction manifests itself. Each exposure may last from ten to fifteen minutes.

During the tentative exposures the distance of the tubal wall from the skin should be four inches, later on it may be reduced to one inch. The vicinity of the irradiated area must be protected. This is done by a thick shield of lead, which if molded properly, attaches itself to the area selected; if not, it must be fastened by a bandage. If the face is concerned, a

sheet of lead, into which a hole is cut to correspond with the area to be irradiated, may be bent over it. During the intervals xeroform salve (1.10 lanolin) should be employed.

An illustration of the deplorable consequences of omission is the suit brought against a prominent physician in Germany who treated a lady for hypertrychosis of the chin for several months. After repeated reactions of a slight nature were observed, the face showed signs of dermatitis of the second degree, while the anterior aspect of the chest developed a burn of the third. After five months cicatrization had taken place in the face. But the chest still showed a large ulceration. At that time the patient brought charges against the physician for criminal negligence.

The court called upon various experts. One was the official court physician, who admitted that he did not understand anything of the Röntgen rays, but gave his official opinion nevertheless. Beside this expert testimony that of the "Governmental medical board of the province" was obtained. None of these testimonies was favorable for the defendant. The third was that of the "Royal medical deputation" of Berlin, which was in favor of the defendant.

The plaintiff recovered judgment to the amount of $75. The points of the complaint were: (1) The insufficient information of the patient in regard to the possible consequences of the treatment; (2) it alleged insufficient protection of those areas which did not require irradiation; (3) the continuation of the treatment after redness had appeared.

The court disregarded the first two points, but sustained the third, viz., negligence.

This judgment is based on an error. If the Court had held that the chest should have been protected it might have been more correct, but it could not have found fault with the continuation of the treatment after slight reaction had shown itself.

In treating malignant diseases, we should be governed by principles which differ entirely from those emphasized in regard to cosmetic treatment. While in the latter instance the area is distinctly circumscribed, in malignant neoplasms the vicinity must be seriously considered at the same time.

Therefore, if the treatment is of a beautifying nature the surrounding tissues must be protected. But nothing is more absurd than protecting an area which needs the influence of a sort of a destroying agent.

In other words, if we are convinced of the fact that even when there is only a small carcinomatous nodule in the mammary gland, the superficial layer of the pectoralis major muscle contains, or may contain, carcinoma cells, why restrict ourselves then, if we attempt to treat a nodule of this kind by the Röntgen rays? Is it not exactly the contrary of what we wish to achieve, if we then prevent distant carcinoma cells from being reached, by covering the vicinity with some impermeable metal? We want to reach *all* carcinoma cells if we can, and the so-called shield does not shield the patient, but the carcinoma cells. Therefore shields off in malignant disease!

If we have made up our mind to influence the carcinoma cells we must employ sufficient energy to enforce this result. This does not imply, however, that the other extreme should be striven for. We must follow our therapeutic strategy in a determined but carefully observant manner. The practical *modus operandi*, therefore, would be about as follows:

The patient suffering from malignant disease is irradiated without first submitting to tentative exposures. The tube should be as near the tumorous area as possible, the distance of the tubal wall from the skin never exceeding two inches.

This is done for the purpose of influencing the growth itself as powerfully as possible. After there is a slight erythematous reaction within the immediate vicinity of the growth, the distance is increased for the following séance. Thus the rays reach a larger surface. In mammary carcinoma, for instance, the area between the sternum and the axilla must be fully exposed. When this wider field becomes erythematous also, the irradiation must be stopped for a few days until it shows signs of disappearance. It is not advisable to wait until the last little sign of dermatitis has vanished, because much valuable time may be lost by waiting. Repeated attacks of dermatitis may thus be endured.

It seems to me that the further the carcinomatous infiltration has extended the more resistance to dermatitis exists, and consequently the less reaction takes place, the cell-metamorphosis lowering the irritability of the skin. This non-susceptibility, of course, varies with the different types of pathological tissue changes. It seems to be greatest in the fibrous type of carcinoma.

In severe cases, and when but little reaction shows after powerful irradiation, the diaphragm (*Münchener medizinische Wochenschrift*, No. 41, 1903) suggested by me should be used in order to concentrate the rays on the tumorous area.

If there be extensive ulceration, causing retention of pus, irradiation should not be continued until the area is made accessible, and any necrotic tissue removed by the scalpel or sharp spoon. If this is omitted, the power of the rays is not only inhibited, but, at the same time, toxæmia from local decomposition is added to cachexia, a very dangerous association indeed. Under exceptional circumstances deep-seated growths, or their remainder after partial removal, may be reached, if the healthy tissues covering them are lifted and reversed so that there is more direct access.

If the integument is concerned, soft tubes must be employed, but deeper infiltration requires tubes of medium hardness. It is obvious that for very deep-seated growths, hard tubes should be employed, in view of their greater penetrative power. But the rays do not in their present capacity possess so much force in the deeper tissues of the body as to induce a complete regressive metamorphosis.

The author does not maintain that the production of dermatitis in the treatment of malignant disease is desirable or a condition *sine quâ non*. But, with our present means, he regards powerful and long irradiation a necessity, and this, unfortunately, entails the prôvocation of the dermatitis.

The author's experience shows that whenever a dermatitis has appeared the size of the growth has diminished, œdema and pain have decreased, and the general condition of the patient has improved.

In spite of extensive dermatitis, which causes a most distressing burning and itching sensation, all patients suffering from malignant disease were anxious to undergo irradiation again as soon as possible. If the *raison d'être* is thoroughly explained to the patients, they will certainly not make their physicians responsible for excessive burns. A patient afflicted with carcinoma, especially if it is inoperable, has indeed nothing to lose, and can well afford the risk of being burned. Will he act like the boy who threw rotten eggs at the man who had dragged him out of the water and saved him from drowning, because in doing so he had pulled out a lock of hair? And in any case the physician is a

soldier and must do his duty unconcerned whether he is applauded or insulted.

Of course, the purely cosmetic standpoint is entirely different. If dermatitis, as alluded to above, occurs in the face of a fair lady who simply wanted to be treated for hypertrichosis, ingratitude will be earned for the removal of the superfluous hair.

As a rule, a séance of ten minutes, repeated every second or third day, suffices. Extensive and deeper-seated growths should be irradiated daily for the same length of time, and if no intense reaction appears, for twenty minutes.

As soon as improvement is noted, the exposures should, for a while, be shorter and the intervals longer. Six weeks after recovery irradiation must be taken up again for a short period.

How far the beneficial influence of inflammation produced by the Röntgen-rays goes is also illustrated by the case of this lady, the wife of a brother physician, to whom we are greatly indebted for kindly presenting herself to you. Her history shows that the first signs of sarcoma of the orbit were observed in the fall of 1901. Enucleation of the eye ball had to be undertaken, but recurrence in the frontal bone took place three months thereafter, and reached such an extent that it was regarded inoperable.

After having ascertained the extent of the growth by a skiagraph, I removed the diseased bone portions first by chisel. Three weeks thereafter, when cicatrization had taken place, irradiation was begun three times a week, exposing ten minutes each time. No change during two months' treatment was observed. But when irradiation was stopped for three weeks, the signs of recurrence showed up again, the vicinity of the orbit projecting far.

Now irradiation was resorted to every day at small distance, low vacuum and high current being chosen. After eleven exposures, extensive dermatitis developed, which proved to be of the ulcerative type, within the center of the irradiated area at the same time complete alopecia at the diseased side set in. The patient suffered considerably for a week, then the symptoms gradually subsided. The treatment consisted in warm applications of Burow's solution at first, and in the use of xeroform gauze later. Three weeks after the beginning of the vehement dermatitis all signs of the sarcomatous infiltration had disappeared, especially the projection and the general condition of the patient improved remarkably. Although during the last few months the irradiation could not be continued regularly, there is perfect euphoria. The signs of cicatrization have disappeared. While there are no evident signs of recurrence, I am not convinced that the sarcoma was cured. I believe that the process was well kept in check by the rays, so that it did not disturb the patient. If you will ask this patient whether she is grateful for having been burned she will unhesitatingly say: "Yes," and she has good reasons for such an answer.

Thus we see that circumstances alter cases. In the meanwhile another miraculous phenomenon makes its appearance on the medical horizon: Little as we know of the practical utilization of radium, yet it marks a new era in science. Its influence upon diseased tissue and its special advantages in little cavities of the body are indisputable, and consequently we shall soon hear of accidents caused by its therapeutic use.

Increased Facilities at Quarantine.—The Finance Committee of the New York State Senate has reported favorably Senator Raines's bill appropriating $50,000 for the quarantine stations and additional buildings at Hoffman and Swinburne islands.

INSOMNIA.*

By ELIOT GORTON, M.D.,
SUMMIT, N. J.

I HAVE selected the subject of Insomnia for this brief address because, whether we are specialists or general practitioners, it is a subject of special interest to us as physicians and one the results and problems of which we all have to face and deal with in the every-day routine of our work. I venture to say that every one here to-night has had—probably has now—cases of insomnia to treat which by their very stubbornness and failure to yield to tried methods have taxed his patience and resources to their utmost. How many times have you thought to yourself or said to a brother practitioner, "Well, I've given that patient everything I know anything about without the least apparent benefit." One may finally dread to see the patient, since he comes day after day with his worried, anxious look and the same old story, "Well, Doctor, I took that medicine last night and it didn't do any good."

Whatever may be our personal opinion regarding the nature of insomnia, there comes a time when, because of the train of symptoms presented, it amounts almost to a disease process. For this reason it is of the greatest importance that we recognize its gravity in its incipiency and institute at once vigorous measures for its relief.

I have no panacea for insomnia. I do know, however, that too much dependence is placed on its purely drug treatment to the exclusion of other equally essential and equally valuable adjuncts to treatment, consisting of hygienic measures, which include baths, and a regulation of the diet and mode of life of the patient. If I shall succeed in presenting to you some principles in the method of treatment which my experience has taught me to value and with some of the points of which you may not be entirely familiar, this paper will have accomplished its object.

The question, What is sleep? confronts us at the very outset of any inquiry into the subject of this paper. Since, however, the question belongs to the physiologists, and since, further, no satisfactory answer is as yet forthcoming from them, I shall not attempt even a definition. I shall, however, ask your attention for a few minutes to the clinical aspect and treatment of insomnia, and I beg your indulgence if what I shall have to say is drawn entirely from an extensive experience in treating a symptom of special prominence in most nervous affections and often a particularly trying one in women suffering from nervous diseases.

First then, in order that we may have a logical and comprehensive sequence, let me refresh your memory with the few facts which are known relative to the physiology of sleep, for these are essential in order that we may have a clear understanding of the elements of treatment. With the incidence of sleep there is contraction of the cerebral vascular system and a consequent diminished flow of blood through the brain tissues. There is also a corresponding dilatation of the vessels of the periphery throughout the body, varying more or less in degree. There is marked slowing of the pulse rate, amounting to eight or ten beats per minute, and the force of the heart's action is diminished. There is deepening and slowing of the respiration with a corresponding retardation of all the metabolic and secretory processes. Further, we should bear in mind the normal sleep rhythm, and by this I mean the normal variations in the degree of intensity or the soundness of sleep throughout a night beginning at 9 P.M. and

*Read before the Practitioners' Club of Newark, N. J.

ending at 6 A.M. In a person in a state of health retiring at 9 P.M. the soundest sleep is recorded from about 10 to 12 P.M. From the latter hour onward the sleep gradually lightens until about 4 A.M., when it again becomes sound for a short period, and is followed by a period during which the sleep is especially light, the individual responding to sensory stimuli of one-fourth the intensity incident to the soundest sleep. In fact, the semi-consciousness of sleep during this period has led many to suppose it to be the soundest. This is due, however, to the pleasurable consciousness of the period. There are, then, two periods during which the sleep in a normal individual is especially deep and these periods are at about 10 o'clock in the evening and four o'clock in the morning. Bear in mind also the changes that take place in the blood-pressure and the cerebral circulation during sleep, and we are at once in a position to understand why certain drugs, the physiologic effect of which is to counteract these normal changes, should not be given.

It is difficult to state in other than a general way the causes leading to sleeplessness. We know that almost all psychoses are accompanied by loss of sleep at some period of the disease. Most cases of mania and neuræsthenia are preceded by a period of prolonged sleeplessness. In many of these cases the insomnia is accompanied by a period of overwork which clearly led to the mental breakdown. Alcoholic and other excesses cause a toxic type of insomnia difficult to control. Mental worry, grief or anxiety, are causes of the first magnitude, and so also is their twin brother, overfatigue. Tea, coffee, opium, particularly its more common alkaloid morphine, are also agents in causation. Like all other symptoms, a consideration of the cause, and its removal if possible, becomes the first object in treatment, but we must remember, however, that sleeplessness soon becomes a habit, and the longer it has been established, the more difficult it is of relief.

As a matter of convenience, we may classify treatment under three general headings—dietetic hygienic, and medicinal—and for the purpose of this paper the dietetic will be included with the hygienic, for they are interdependent.

The hygienic treatment, so often neglected and which in many cases is of far more value than the medicinal, consists in the use of the various hydrotherapeutic measures, such as the warm full bath, cold pack, sitz bath, foot bath, the cold rub, the ingestion of hot drinks, and regulation of the mode of life.

The medicinal treatment consists in the regulation of the alimentary tract and the exhibition of medicines, the physiologic effect of which is to produce sleep, the more important being paraldehyde, trional, sulphonal, chloral, and the bromides.

Insomnia in its incipiency usually yields readily to treatment, but we are chiefly concerned with those stubborn and distressing cases of long standing, in which the cause cannot be determined, or, if known, cannot be corrected, and a persistent and judicious combination of the various methods must be tried.

In many cases the first requisite in treatment is change of scene, of surroundings, of environment, and this in itself is often all that is necessary. The getting away from the stress of life, from business cares and worries, from the depressing influence of well-meaning but tactless relatives or friends is often imperative, and this is a fact which should be more generally insisted upon. However, a man feels that he is essential to his business and cannot leave it; a woman cannot leave her children; often the financial problem cannot be surmounted, and so the matter drags along until a point is reached where something *must* be done, and sacrifices are made which could have been avoided had the situation been controlled by a firm hand at the outset.

Let us take, as an example, the treatment of the insomnia due to alcohol and its concomitant excesses. To begin with, these cases must be absolutely under control, and for obvious reasons are difficult to treat at home. The withdrawal of liquor, at once if possible, but gradually if we must; the administration of a purge toward regulating the functions of the alimentary tract; a light but nourishing diet for the first few days; a tonic regime with a tonic bath such as the drip sheet or half bath followed by vigorous rubbing; hot milk between meals; moderate exercise; massage; the warm, full bath at night, twenty minutes in duration, or a cold pack of one hour's duration, followed by a glass of hot milk or malted milk, constitutes a satisfactory regime. Medicinally, the hypnotic "par excellence" is paraldehyde. Given in two to three drachm doses and repeated in an hour if necessary, it usually is followed by a quiet sleep from which the patient will awaken refreshed and decidedly improved. The rationale of this combined treatment is, concisely, as follows: Constipation is relieved, and any possibly toxic material cleared from the alimentary tract. As the stomach is usually irritable, a light nourishing diet is essential. As a nervine, strychnine sulph., gr. $\frac{1}{30}$, or larger doses, four times daily, is excellent on account of its stimulating and steadying effect. The drip sheet or half bath in the morning for its tonic effect upon the nervous system and to stimulate the eliminative function of the skin. Hot milk, bouillon or broth, between meals to allay the craving for stimulants and prevent the stomach from becoming empty, thus relieving the tendency to nausea and the feeling of "goneness" so commonly complained of. Moderate exercise and massage for its beneficial effect upon the muscular and circulatory systems. The warm, full bath or the cold pack at bedtime to assist one of the normal processes incident to sleep, the dilatation of the peripheral vessels. Paraldehyde for its somnific effect upon the brain and nervous tissue. I have gone fully into details because this is quite a typical form of insomnia, and the treatment as outlined, with modifications to fit existing conditions, may be applied to other forms.

I shall only outline the various methods of treatment in a general way, since individual cases differ so widely that the form of treatment best adapted for any given case becomes often a matter of judgment on the part of the attending physician. In the majority of cases the hygienic and medicinal treatment dovetail into each other in such manner as to make them interdependent, and success often follows their combined use when either one separately will fail. Where baths are used, the technique of administration is all important and failures are often attributable to its non-observance.

The warm, full bath given just before retiring, followed immediately by a hot drink and a hypnotic in moderate dose, is of great value. In the administration of the bath the patient's face should be bathed with cold water, and the head above the eyes enveloped in a towel wrung out of cold water. This is an important and necessary point in technique which is usually neglected. It prevents cerebral congestion and the sensation of vertigo which often follows the prolonged warm bath if given without the cold head compress. The patient should lie in the bath quietly, the duration should be from fifteen to twenty-five minutes and the water should be kept at the temperature of 98°. After emerging from the tub the patient must not be rubbed dry, for rubbing

has an exciting effect. The excess of water should be wiped away quickly and the patient put at once into bed and given a glass of hot milk and the hypnotic selected. The milk or hot drink must be so hot that it can only be sipped.

The cold, wet pack is equally efficacious. Here again the first requisite is the cold head compress and the bathing of the face. The sensation of cold disappears in a few minutes, since the radiation of heat is prevented by the blankets in which the patient is wrapped. There follows marked dilatation of the peripheral vascular system, and the resulting brain anæmia produces drowsiness and a marked slowing of the heart's action. As a result of the complete muscular rest a state of tranquility develops, and in most cases sleep follows. I have seen excited, sleepless patients and chronic cases of insomnia go to sleep in the pack and sleep throughout it. The technique must be rigidly adhered to else failure follows. When correctly applied, the patient is very comfortable after the first few minutes, and the usual duration is from one to two hours. If, however, the patient goes to sleep in the pack the duration can be prolonged. The sheet should be wrung out of water at a temperature of 70°.

Warm sitz baths, 95°, of twenty minutes to an hour in duration, exert a distinctly sedative and anodyne effect. This bath may also be used cold, 50° to 68°, two to five minutes' duration, with the same effect, for the reaction which brings about a flow of blood to the abdomen depletes the cerebral circulation. The cold sitz bath is contraindicated in acute inflammatory processes of the abdominal or pelvic organs.

The foot-bath is another valuable adjunct to the treatment of insomnia, and its beneficial effect is often surprising. Again, cooling of the head is indispensable. Both high and low temperatures are employed, 104° to 54°. The feet are immersed in water which must be kept at the desired temperature, and the bath continued until the feet are intensely red. The patient should stand in the bath, rubbing one foot upon the other. It is of especial value in neurasthenic insomnia or any condition caused by cerebral congestion and will often induce sleep without the aid of drugs.

These are simple hygienic measures of proved value, which may be instituted in any home with a bath tub. The depletion of the cerebral circulation is the principle underlying these procedures, and cases of insomnia due to a loss of vascular tone in the cerebral circulation, and in which the patient seems most wakeful in the recumbent position, respond immediately to these measures.

A review of the more serviceable hypnotics will not be out of place. Paraldehyde, on account of its pungent, disagreeable odor and taste, is prescribed very little in private practice, although it is one of the best and safest hypnotics at our command. It is invaluable in alcoholic insomnia, and almost equally valuable in the treatment of other forms. It should be given in 2-drachm doses if the desired effect is to be obtained, and this dose can be repeated in an hour if necessary. An irritable stomach usually contraindicates its use. A favorite method of combining paraldehyde so as to make its pungent odor and taste less objectionable, is as follows: Paraldehyde, two parts; whiskey, one part; syrup of orange, one part. This mixture separates into its component parts on standing and must therefore be well shaken just before dispensing. Each tablespoonful represents two drachms of the drug. In alcoholics particularly this remedy is far superior to the chloral and bromide mixture, both in effect and result, for it has no depressing after-effect, does not affect the heart and does not lock up the secretions—a point of much importance. In fifteen years I have seen but one habit case.

Trional is another popular hypnotic which is extensively used. The dose ranges from 15 to 30 grains, but the best effect is obtained from the smaller dose, repeated in an hour if necessary. It is slow in action, and should be given from one to two hours before bedtime. It is not soluble, and the dose is usually placed dry on the tongue, followed by a drink of water or hot milk. If, however, a dose of 25 grains does not induce sleep after the third or fourth trial, it is useless except it be assisted by some other drug or method. It also has the advantage of being fairly free from any unpleasant after-effect, with no danger of habit formation if used in the smaller doses. Large doses often seem to have a cumulative action and induce sleep twelve hours or more after administration.

Sulfonal is also extensively used with varying results. It is generally given in 15-grain doses dissolved in hot milk. It often has a depressing and unpleasant after-effect and a tendency to check secretion. I have had several patients with an idiosyncrasy for this drug, who could not take it even in small doses without becoming very wakeful and breaking out in the morning with an extremely annoying rash resembling measles. For this reason I seldom prescribe it until I have failed with others.

Chloral you are familiar with; its advantages and disadvantages; its unpleasant after-effect, its danger of habit formation.

The bromides have their sphere of usefulness also, but are usually combined with other drugs or methods. They are contraindicated in digestive disturbances. When bromide is used for the relief of insomnia in 40 to 60-grain doses, it should always be followed the next day by the half bath. This enhances its value, makes the patient more tolerant, and by rendering the skin active, the unsightly and disagreeable acne following its use can be readily controlled. If a patient is especially susceptible to bromide, a smaller dose may be effectively given if all salt be withdrawn from the food.

Opium and its alkaloids should not be given for insomnia. Small doses stimulate and excite the nervous system, producing a condition of wakefulness in the majority of cases, while larger doses present disagreeable after-effects. The results from its use are often more difficult to deal with than the affection itself.

I shall not take your time further for the enumeration of other hypnotics. Their name is legion and but few are of any real value. Our time is too valuable and our patient's case often too urgent to permit of much experimentation, so we are inclined to hold to the remedies and methods with which we have been more or less successful and the value of which we have proven.

There is one combination of hypnotics I desire to call your attention to. In cases in which the methods you have tried have been of no avail, give 10 gr. of sulfonal in hot milk at 6 P.M., 15 gr. of trional at 8 P.M., and the warm full bath with 40 gr. of bromide and a glass of hot milk at 9 P.M. Your patient will live through it and may have a good night's rest.

There is a form of insomnia caused by overfatigue, the rational treatment of which does not include any of these drugs. I refer particularly to physical rather than mental overfatigue, although the simpler form of the latter is also amenable to the same treatment. If we can reduce this excessive fatigue to one of simple fatigue our patient will sleep. This can be accomplished by the ex-

hibition of a mild stimulant such as strychnine, or a glass of ale or porter. Hot milk or hot malted milk is also of great service. The stimulating effect of the half bath, or a simple cold dip, often acts like magic in these cases. I cannot explain this satisfactorily on the basis of any of the known facts pertaining to the physiology of sleep, but I do know that these measures will induce sleep. I regard the exclusion of tea and coffee as imperative in the management of most cases, nor do I think it wise to allow chocolate or cocoa to be substituted. Although they contain much less caffeine or allied alkaloids, nevertheless I have seen cases which received sufficient to cause pronounced wakefulness. Drinks of this character should at least be excluded from the evening meal. In this connection, my experience has been that a light evening meal, taken early, is most conducive to a restful night. This may be supplemented by a walk in the evening an hour before retiring. Under no circumstances should the patient be allowed to continue his accustomed work into the evening hours, as this is especially conducive to wakefulness.

The treatment of insomnia will depend primarily upon the treatment of the disease from which the patient is suffering. In many cases of simple neurasthenia, the treatment of the disease practically resolves itself into the treatment of this one symptom. Under any circumstances the nervous case is the one most difficult to treat, and I consider that form of treatment as most successful which will cause the patient to sleep without the administration of drugs. I insist, however, that the measures I have described will materially reduce the drug dosage and induce a sleep which to all intents and purposes is normal in character. We may thus avoid the objectionable after effects which follow large doses of hypnotics.

Fair Oaks Sanatorium.

COMMON DUCT STONE ASSOCIATED WITH ACUTE SEPTIC CHOLANGITIS.

By GEORGE EMERSON BREWER, M.D.,
NEW YORK.

The object of this communication is to report and place on record the histories of three cases of common duct stone, associated with symptoms of grave sepsis.

While it is generally recognized that jaundice and pain are the commonest and often the only symptoms indicating the presence of a stone in the common bile duct, it is not as well recognized that a certain small number of these cases present in addition chills, fever, and sweating, so characteristically intermittent in character as strongly to suggest a malarial infection.

To this group of symptoms the term *fièvre intermittente hépatique* was first applied by Monneret. Since that tiem the condition has been studied and accurately described by Charcot, Osler, and a number of others, and its association with the presence of a foreign body in the common or hepatic ducts has been verified.

Considerable difference of opinion has existed in the past regarding the etiology of the septic symptoms, some authorities holding that the febrile crises were due to bile absorption, through abrasions in the duct mucous membrane produced by the foreign body; while others regarded them as of nervous origin and similar in character to some of the varieties of urethral fever.

Most modern observers, however, regard the condition as one of septic absorption from infection of the duct—a true infectious cholangitis. This view is strengthened by the fact that in the severe and neglected cases, the ducts are thickened and hyperæmic, the liver the seat of multiple abscesses, and the bile changed in appearance by the presence of pus and blood.

The condition is one of great gravity, and unless promptly relieved by surgical means, leads, almost invariably, to a fatal termination.

In many instances the diagnosis of malaria with catarrhal jaundice is made and much valuable time is lost by a long course of useless treatment by quinine and other drugs. The only treatment that can hold out any hope of success is surgical, choledochotomy, removal of the stones, and hepaticus drainage.

The following three cases are the only examples of this condition which have been recognized and operated upon by the writer, and they represent, approximately, three grades of virulence:

Case I.—G. M., male, aged fifty-two years. For several years this patient has complained of characteristic attacks of gallstone colic. Was jaundiced ten years ago. He was first seen by the writer in the winter of 1902. At that time he was moderately jaundiced and complained of occasional attacks of pain in the upper right quadrant of the abdomen, which were accompanied by chills and fever. There was tenderness over the region of the gall-bladder, but no palpable tumor. The diagnosis of a common duct stone was made and an operation advised. Operation was refused and the patient disappeared from observation. One year later the patient was again seen in consultation. At this time he was deeply jaundiced and complained of moderate pain in the region of the gall-bladder, which frequently became accentuated. With the increase in pain, there was usually a chill followed by high fever and sweating. The patient looked pale and haggard. There was a moderate leucocytosis, but no malarial organisms in the blood. Operation was advised, and as the patient's sufferings were great, and as he was gradually becoming more septic, the advice was accepted, and he went immediately to the Roosevelt Hospital

Under ether anæsthesia an incision eight inches in length was made over the right rectus muscle. The gall-bladder was thickened and contained thirty-five large and small calculi, together with a quantity of turbid bile. In the common duct there were found two calculi, each about the size of a small hazelnut. These were removed, the patency of the duct established by the passage of a probe into the duodenum, and the hepatic duct drained by the Mayo method. (This consisted in the introduction of a small rubber tube into the hepaticus, through the wound in the common duct. The wound is then partly closed by introducing two catgut sutures longitudinally on either side of the incision, and tying the opposite ends across the duct. A small strip of gauze is then placed over the closed wound, and secured by again tying the uncut ends of the catgut sutures over it. The free ends of the rubber tube and strips of gauze are brought out of the abdomen opening.) The calculi were next removed from the gall-bladder, which was also drained by a rubber tube introduced and held in place by two purse-string sutures. The abdominal wound was partly closed, an opening being left for the exit of the gall-bladder and duct drains. The patient's temperature remained elevated for ten days or two weeks, during which period there was an abundant flow of bile from the wound. All drainage was removed at the end of the second week. The gall-bladder wound closed promptly, but there was continual leakage from the

duct. At the end of ten days bile began to appear in the stools. About the second week the jaundice began to disappear slowly, but was practically gone at the time of complete healing of the wound, which took place about six weeks after the operation. He has since been in perfect health.

Case II.—J. M., female, aged sixty-six years. Was admitted to the surgical division of the City Hospital in February last. The patient had the history of gallstone colic, extending over a number of years. About six months before her admission, she became jaundiced. There was constant pain in the region of the gall-bladder, with the loss of weight and strength. During the last three months, she had been having irregular attacks of acute pain accompanied by vomiting, chills, high fever, sweats, and an increase in the jaundice. Operation was advised, but for one reason or another was postponed for three months, until her admission to the writer's service. At the time of her admission, the patient was thin, weak and bed-ridden. There was deep icterus, and the attacks of fever occurred, practically, every day.

An incision eight inches in length was made over the outer border of the right rectus muscle. The gall-bladder was found to be normal and was not opened. The common duct contained a large movable stone, which was extracted through a longitudinal incision. Hepaticus drainage was established by the introduction of a small rubber tube through the opening in the common duct. This was accompanied by a strip of gauze, held in place by the Mayo method. The abdominal wound was partly closed and dressings applied. She made a tardy though complete recovery. The drains were removed at the end of fourteen days, but the abdominal wound was packed until complete cessation of bile leakage, which persisted for about four weeks. All septic symptoms immediately disappeared after the operation, and she made a complete recovery.

Case III.—C. K., female, aged thirty-six years, was admitted to Roosevelt Hospital in the autumn of 1902, suffering from symptoms of grave sepsis. There was an indefinite history of abdominal pain, extending over a number of months. At the beginning of the present attack there had been pain, fever, and slight jaundice. Her condition rapidly grew worse and there developed a moderate distention of the abdomen. On admission her temperature was 105°, her pulse, in the neighborhood of 140, weak and irregular. There was also moderate jaundice, nausea, vomiting, tenderness, and rigidity over the upper half of the right rectus muscle. Her condition was such that operation at the time was deemed unadvisable. The following day, however, there was marked improvement in all her symptoms. A more careful examination was undertaken, and the diagnosis of septic cholangitis made with the probable presence of stone in the common duct. The symptoms which led to the diagnosis of cholangitis were, pain and tenderness in the epigastric region, the absence of signs over the region of the gall-bladder, the presence of tenderness over the liver (elicited by forcibly compressing the lower thorax with the hands, placed over the ribs on either side), general sepsis, and jaundice.

Under ether anæsthesia, an incision was made over the outer border of the right rectus muscle. The gall-bladder was distended and contained several small calculi. There was a large, round stone in the common duct which was removed through a longitudinal incision. Following the removal of the stone, a large amount of opaque dirty pinkish fluid, consisting of a mixture of blood, pus and bile, escaped from the common duct. This was promptly removed by careful sponging, and the entire region disinfected by a general use of peroxide of hydrogen and salt solution. Hepaticus drainage was established, and the wound partly closed, a large drainage tube being also left in the gall-bladder. Following the operation, there was an immediate improvement in all the septic symptoms. The tube, in the common duct, was removed in about ten days, that in the gall-bladder was allowed to remain somewhat longer. She made a complete recovery, and was discharged at the end of five weeks.

It is interesting to note that in the first two cases there were no gross changes in the walls of the ducts, and the bile appeared normal in color; in the last case the ducts were thickened and œdematous, the liver enlarged, and the bile opaque, thick, ropy and of a dirty, pinkish color.

In the first two cases the acute symptoms had existed for several weeks, and the progress of the septic intoxication was gradual; while in the latter case the symptoms were grave and alarming from the first, and the progress of the sepsis was rapid. In the milder cases, without gross changes in the bile or ducts, it is probable that the infecting agent is one of low virulence, and that the lesion is limited to the larger ducts.

These patients, if unrelieved, suffer greatly, and eventually die from a combination of exhaustion, sepsis, and cholæmia. In the severe type of the disease, the patients die promptly, unless relieved at a very early period, and the autopsies show a septic and often virulent cholangitis, œdema of the liver, and innumerable small abscesses.

In practically all of these cases the stone is a movable one, and the complete obstruction to the flow of bile to the intestine when present is due to swelling and œdema of the mucous membrane, evidenced by the fact that bile is often completely absent from the stools for several days or weeks after removal of the stone.

This fact emphasizes the importance of hepaticus drainage in all cases.

A CASE OF CHOROIDAL INFLAMMATION, WITH PERMANENT LOSS OF VISION, CAUSED BY EXCESSIVE USE OF THE EYES DURING A COMPARATIVELY SHORT PERIOD OF TIME.

[By] D. B. ST. JOHN ROOSA, M.D.,
NEW YORK.

On the 3d of October, 1896, I was consulted on account of impaired vision, by a physician, forty-six years of age, practising near New York City, who gave me the following history:

While attending a patient, a confinement case, where he was obliged to wait for a period of more than twelve hours, he passed, as he thinks, ten hours of the time almost continuously in reading a book or two books printed in rather, but not excessively, small type. He is confident that his vision up to that period was excellent in each eye, for besides his ordinary employment as a physician, he tested his eyes frequently in shooting. On the next morning after this period of reading occurred, he found a blur, apparently over both eyes, but finally he settled down to the conclusion that it was confined to the right eye. It was very disturbing. He considered himself overworked, and he took a trip on the water and was exposed to the glare, without any particular pains being taken to prevent its influence on his eyes. The blur continued about the same during his trip and on his return home. About six weeks after the failure of his sight, he sought my

advice. I found his vision was $\frac{20}{50}$ in the right eye, in the left eye $\frac{20}{70}$, that the vitreous humor of the right eye was hazy, so that no good view could be obtained back of it. I prescribed for him, but finding that he did not grow worse, he did not consult me again until the 10th of January, 1898, when I found exactly the same vision, the right eye, $\frac{20}{50}$, the left $\frac{20}{70}$. He complained of the same subjective blur, which he insisted had never changed since the morning after the exposure of his eyes to prolonged use. I then found, on ophthalmoscopic examination, that the vitreous had quite cleared up, but there were several spots of choroidal atrophy over which the retinal vessels passed. The patient was continuing his occupation as a physician, besides being somewhat interested as a municipal officer in a small city, and had no particular inconvenience, except that he always has what he called a blind spot in his right eye, as at his visit in 1896. On the 19th of December, 1903, the doctor again consulted me, and I found his vision exactly the same with the right eye, rather better with the left, it being indicated by the fraction $\frac{20}{15}$. The ophthalmoscope showed the same extensive choroidal changes—atrophy in the right eye. The left fundus oculi appeared to me to be normal. The patient came at this time to be fitted with glasses for reading, he having become very presbyopic.

Remarks.—Although continuous use of the eyes on small objects is constantly enumerated in textbooks as one of the causes of inflammatory action in the eyeball, such a result is really seldom seen by the oculist. One of the reasons may be that the asthenopia, which generally follows excessive use, usually causes patients to desist from undue occupation with their eyes, before the danger line has been crossed. Naturally, exceptions to this condition are made in the case of myopes, for myopia is itself an inflammatory condition; but I am referring now to persons who start with emmetropic, or hypermetropic, or slightly hypermetropic, and sound eyes. The relation of cause to effect in the case I am reporting is pretty distinct. The observer was intelligent, had good occasion to watch his vision in his occupations, and states distinctly that he never felt the blur until the morning after this continued use. Probably the choroiditis was set up at that time. It is also remarkable, in this case, that the disease came to an immediate standstill, so far as impairing the function of vision is concerned. One would have expected that the choroiditis would advance, as the patient took no extraordinary means to protect his eyes from this danger. On the other hand, his sea trip was just what an oculist would not have advised. It is interesting to note that the retina has not been invaded, to any very considerable degree at least, by this inflammatory action. The process attacked the vascular part of the eyeball, and immediately invaded the vitreous, causing the hyalitis, which was all there was to be seen on the first examination in 1896. It is also interesting to note, as it seems to me, that this is a traumatism rather than an infection of the eye. In later times, with our advanced knowledge in infectious diseases, we sometimes are inclined to ignore primary, mechanical and chemical causes, which apparently produce conditions entirely similar to those from pure infection.

20 EAST THIRTIETH STREET.

German Degree for an American Woman Chemist.—A young lady from Detroit, Miss Mowbray, has received the degree of doctor of science, *magna cum laude*, from the University of Berlin. She is the first woman chemist to whom the university has granted the degree.

Chronic Tonsillitis—G. D. Murray lays stress on the following points: The teeth should receive attention from infancy, also that the tongue when coated should be cleaned as carefully as the teeth. The mouth is a primary cause of tonsillitis and ought to receive simultaneous treatment with the throat. Offensive breath, from microorganisms present in the mouth and throat, *can be eliminated* through the personal effort of the patient. Bad taste in the mouth, particularly before meals, suggests infection of the tonsils, decomposing epithelium débris on the tongue, gums, teeth, and oropharynx—one or all. This filth (in which Sternberg found forty-two different varieties of microorganism) ought to be cleaned and sterilized several times daily by the patient. Diseased tonsils, not necessarily enlarged, and often hidden, no longer act as a barrier to disease, but rather as a germ incubator and ought to be removed. No method of removing the tonsils is a safeguard against dangerous hemorrhage when one operates on a bleeder.—*The Laryngoscope.*

A New Method for Diagnosing Fractures.—Plesch has found that any injury to or disease of a bone impairs its conducting power for sound, and hence modifies the percussion note heard over it with a stethoscope. If one epiphysis of a long bone is percussed while the other is being auscultated, the note is perfectly transmitted if the bone is intact. If it is fissured, the note becomes muffled and a metallic ring may be heard; while if it should be fractured, conduction ceases. In practice it is best to use the epiphyses of the long bones for percussion, though if these are not accessible, the epiphysis of the adjoining bone may be used, as the sound is well transmitted across joints. In cases of fracture by beginning to auscultate distally to the supposed seat of injury, and gradually approaching the point of percussion the spot at which the note first becomes audible indicates the position of the fracture. The author describes in detail the method to be followed for the different bones, and emphasizes the value of the method in such difficult cases as subcutaneous fractures of the cranium and fractures of the neck of the femor.—*Deutsche Zeitschrift für Chirurgie.*

A Lecture on the Mental Disorders Associated with Decay.—G. H. Savage declares that premature senility produces exactly the same symptoms to which ordinary senility gives rise. The mental disorder of premature senility may be induced by worry, but much more commonly it is dependent upon alcohol, and very commonly upon syphilis. The insanities of decay and old age occur at any age—from thirty to ninety. The time of their appearance depends not only upon the hereditary constitution of the individual but upon his surroundings. Although loss of memory is about the most characteristic defect associated with senility, it is not always in direct relationship to decay of the brain. One of the points of characteristic difference between general paralysis of the insane and senile decay is, that in senile decay the memory fails so much more markedly and completely than it does in general paralysis of the insane. Another important point to remember in considering the vagaries of memory among old men, is that you may get an accentuation of the old memories, so that they are brought out more clearly. In senile mania, there is not infrequently great exaltation of ideas, a great amount of boastfulness. Again, some of the most difficult cases are those of senile epilepsy. Probably one of the most common forms of mental disorder associated with senile decay is melancholia in one or other of its forms. One of the not uncommon symptoms of progressive senile decay is hallucinations. A considerable number of patients pass into a state of mental weakness after apoplexy. The writer sums up the most characteristic forms of mental disorder as: simple dementia, loss of higher control, as evidenced in maniacal outbursts and acts of indecent exposure; and finally senile dementia of the hypochondriacal type, which is often associated with ideas of obstruction.—*The Practitioner.*

MEDICAL RECORD:

THE PROGRESS OF CANCER INVESTIGATION.

THE announcement from London, by three observers, of the discovery of an important fact in the histology of malignant growths, and the corroboration of this discovery by two other gentlemen in a paper read before the Royal Society on January 21, has stimulated our ever-present interest in this matter, and has opened a hopeful path for further investigation. The two last-mentioned gentlemen, Doctor Bashford and Mr. Murray, have been studying the method of cell division in normal and in proliferating cells, and have embodied their results in the paper mentioned above. These results bear heavily against the hypothesis of the parasitic origin of cancer, and in favor of the view that malignant growths are due to perverted cellular growth and proliferation. These observers have devoted most of their attention to the physiology of nuclear division, which, it is needless to say, is the most important part of the process of cell-division, and is a subject which has attracted a large amount of attention during the past few years. In a few words, this new discovery may be described as follows: observation has shown that, during the process of karyokinesis, the nucleus of a typical cell in ordinary human tissue under normal circumstances divides with the formation of thirty-two chronosomes, one-half of which gather themselves about each nuclear pole, and eventually form the nucleus of the new cell, the body of which is formed by one-half of the protoplasm of the original cell. Certain cells in the body, concerned in the process of reproduction, have been found to show only sixteen chronosomes during nuclear division, and to exhibit a different karyokinetic figure from that seen in ordinary cells. When such cells meet their physiological complements the normal number of chronosomes for the particular species is restored, and cellular reproduction proceeds in the usual way. Such cells are said to be gametogenic. The English observers have shown that in cancer cells from various sources sixteen is the usual number of chronosomes, and that in other ways cancer cells resemble the gametogenic cells. They have consequently suggested the word "gametoid" to describe such abnormal growth as is seen in the cells of a malignant neoplasm.

The practical indication of this discovery is that under certain forms of irritation or stimulus the normal cells of the body will change their mode of proliferation, will assume characteristics which do not properly belong to them, and in some of their vital processes will approach those of normal gametogenic cells which are known to be extremely active. When a normal cell acquires such qualities it becomes able to proliferate with great rapidity, to invade surrounding tissue with its cellular progeny, and, apparently, to engraft its abnormal powers upon cells in its neighborhood, not its descendants. Such characteristics are those which, judging them by their results, we call malignant, and this new discovery emphasizes what pathologists have become more and more impressed with, that the study of the most minute and recondite cell processes, is what may sometime lead us to a clear understanding of what malignant neoplastic growth really is, and may perhaps indicate means for the control of such processes.

This discovery does not offer us anything new in therapeusis, but it is an advance in positive knowledge, and as such forms an element in a structure which we may reasonably hope to build to contain the means for a successful contention with the scourge of malignant disease. It may also prove an efficient means for the differential diagnosis of neoplasms, for according to its testimony the cells of a malignant growth ought to contain sixteen chromosomes and those of a benign tumor, the usual thirty-two, for the human species.

The theory that cancer originates in latent embryonal tissue, suddenly stimulated into activity and perverse growth in some unknown way, does not appear to receive any support from the discovery which we are discussing, and in our opinion further investigations will make this theory still less tenable. There is no reason for assuming the existence of embryonal tissue as the basis of a malignant growth when all the phenomena can more satisfactorily be explained by the theory that malignant characteristics are developed in cells of various normal and properly placed tissues by some so far undiscovered stimulation which causes a perverted and luxuriant proliferation. Malignant degeneration may occur in embryonic tissue, but that is clearly not to be cited as proof that embryonal tissue is the only source of malignant disease. Such occurrences mean simply that the embryonal cells have been subjected to the same form of stimulation or irritation which produces malignant proliferation in the case of other cellular tissue.

By this discovery, additional proof of correctness is afforded to the theory that cancer, both carcinoma and sarcoma, has for its basis a form of perverted cell activity which results in luxuriant proliferation, reversion to an atypical course of growth, and the ability to invade surrounding cellular structures, imposing its characteristics upon them. We believe that this peculiar form of activity is caused by some form of stimulus or irritation, but of even the approximate character of this we are so far ignorant. We are not referring now to coarse forms of physical irritation exemplified in the causation of epithelioma of the lip, but to some sort of action not improbably brought about by chemical or physiochemical changes in the blood, which is thus unable to supply the cells of the tissue with their normal nutriment. A most hopeful line of investigation seems to be opened by the discovery announced by our English confrères, and we look forward with interest to further developments. The life history of the cancer cell promises to be most rigidly investigated, and it will be the imperfections in our technique

and the inherent difficulties of the subject rather than lack of enthusiasm which will make our progress halting and uncertain. A fruitful but exceedingly difficult field for work is in the subject of the metabolism of the cells of neoplasms, and any knowledge gained here might assist us to the important goal for which all are striving—efficient therapeusis.

SANATORIA FOR CONSUMPTIVES.

SINCE the time when tuberculosis was recognized as a disease which could be both prevented and cured, the most scientific means have been employed to prevent and treat the malady. Hospitals have been erected for the sole behoof of consumptives, wards have been set apart in existing institutions for tuberculous patients, and the dispensary system of home treatment of those suffering from the disease who are unable to pay, has been initiated in a number of the large towns of the civilized world. Common sense and rational modes of treating and preventing consumption are now in vogue. No longer is the patient shut up in a close, ill-ventilated room, from which all fresh air was rigidly excluded, but is treated by methods exactly the converse. Fresh air and sunlight are now appreciated at their true worth, and their curative value to the consumptive has been of late so frequently demonstrated that even the most skeptical and conservative physicians have been compelled to declare themselves converts to the new views. With the rise and general adoption of these principles of treatment came, naturally, the sanatorium movement. It was felt that in order to get the best results from treating consumption on these lines, special buildings must be erected in which patients would have to conform to certain rules as to diet and manner of living generally.

The leading principle of all sanatoria was that the inmates should breathe all the fresh air possible and that advantage should be taken of whatever sunlight there might be. This complete upheaval of old-time notions was at first received with little favor; it was regarded as but another fad, and predictions were freely made that after the enthusiasm which usually accompanies a revolution had died out, that reason would once again assert her supremacy and we should revert to the old order of things. So far, however, from such being the case, sanatoria have sprung up on every side and have flourished abundantly, and the only fear now is that this method of treatment is being overdone, and that these institutions, instead of being regarded as but one means to the end, are now looked upon as the only salvation of the consumptive and as the only way of checking the spread of the disease. The truth is that sanatorium treatment is most decidedly an important factor in the crusade against tuberculosis, but at the same time it is but one factor. There are other measures to be taken which oppose very largely in bringing the fight to a successful issue.

Dr. Arnold C. Klebs of Chicago read a paper at the annual meeting of the Minnesota State Sanitary Association at St. Paul, December 18, 1902, in which he sets forth his views as to sanatoria and hospitals for consumptives. In his opinion the principal factors of the sanatorium régime are: persistent open-air life, abundant alimentation, hydrotherapeutic measures, and a general hygienic regulation of the patient's daily life, always adapted to the requirements of the individual cases, to be ascertained by constant medical supervision. With regard to the necessity of an open-air life for the consumptive, there is such perfect agreement among medical men on this point that it would be waste of time to dwell on the matter.

Dr. Klebs, however, does not believe in the absolute "Rest Cure" as practised in modern sanatoria, but thinks that with careful selection of cases, many patients could be occupied in some way, useful and diverting to them, without interfering in the least with their progress toward recovery.

As to the alimentation of the consumptive, a considerable diversity of opinion exists. In the majority of German sanatoria it is the custom to stuff the patients, compelling them to eat a certain large quantity of food regardless of their feelings or the condition of their stomachs. The MEDICAL RECORD has more than once commented adversely on this practice, rather believing that a smaller quantity of food well-digested will do the consumptive more good than to overload his stomach. Dr. Klebs, while insisting that it is to the great benefit of a tuberculous patient to eat well, does not mention the subject of forced feeding. He, nevertheless, declares himself in favor of a generous and varied diet, and is of the opinion that a good cook in a sanatorium ought to have a position of greater importance than the head nurse.

The author advocates hydrotherapeutic measures as a factor of the régime of great benefit, and states that they should not be neglected, but must enter naturally into the patient's daily life.

Dr. Klebs ends an interesting and illuminative paper with these conclusions: "The spread of the disease can be prevented by general education of the public about the nature of the disease, and its dangers, its method of spread, about the factors which predispose to the disease, and the importance of hygiene and cleanliness. Such education should address itself chiefly to those whose position gives them influence over others, as parents, teachers, superintendents of industrial companies, and last, not least, physicians. More importance ought to be given to this subject in the curriculum of medical schools. The State or city through its Board of Health ought to investigate and enforce improvements of sanitary condition of private and public buildings, and not only issue, but enforce, anti-spitting ordinances. It should enforce notification of cases of open tuberculosis, or at least advanced cases, and the disinfection of dwellings in which patients with tuberculosis have died. The enforcement of pure-food laws and the supervision of the milk supply belong also here.

"Special dispensaries for tuberculous patients should have offices in the different parts of the city. There applicants could be examined, advised and treated, and the offices could keep in touch with the houses of such patients through visiting nurses. The offices also should supply patients with cuspidors, bandage material and special foods, free or at a nominal price. They should select cases for sanatorium treatment, send advanced cases for isolation to hospitals or asylums, should remove children from tuberculous parents, and by keeping records of the

different cases and their houses, might direct the attention of the authorities in the direction where sanitary improvements have to be enforced."

The *British Medical Journal*, January 9, contains a leading article on sanatoria for consumptives, in which the question is discussed as to whether this manner of treatment has produced the good results claimed for it. "To an enquiry made," says the article referred to, "by a German assurance society with regard to the state of consumptives who had been treated in sanatoria between 1893 and 1897, 1336 replies were received, which were classified as follows: 257, or 19.2 per cent. were dead, 120 or 9 per cent. were unable to work, and 950 were able to work partially or completely." The statistics from Goebersdorf give similar results, while Englemann gives somewhat more satisfactory figures.

The lesson to be learned from a consideration of treatment of consumptives by means of sanatoria, thinks the writer of the *British Medical Journal* article, is as follows: "The natural process of recovery from definite phthisis probably requires three years rather than the regulation three months. For the well-to-do who can afford protracted treatment on sanatorium lines the method is an immense gain; while for the favored few among the poor who can obtain the full treatment for a sufficient time the method is equally of priceless value. For the great majority, however, a three months' course of sanatorium treatment, if it be immediately followed by a return to ordinary life, cannot be relied on to afford lasting relief."

Educating the mass of the people how to prevent the disease is the most important factor in the crusade against consumption. Sanatoria are a useful means of treating those afflicted, but the value of such institutions has been exaggerated. Greater care, too, might be exercised in selecting cases suitable for sanatorium treatment. The early stages of tuberculosis is the only form which is likely to receive marked benefit in sanatoria for the consumptive poor.

Health of the Japanese Navy.

The last report published on this subject gives details of the sanitary conditions of the Japanese Navy during the year 1901. The state of affairs now prevailing in the Far East lends especial interest to everything that concerns the fighting forces of Japan.

It appears that the mean daily force in the Japanese service for the year 1901 was 26,469 persons, showing an increase of 3,172 as compared with the preceding year.

The total number of cases of disease and injury entered on the sick list was 24,954, a ratio of 942.76 per 1,000 of force, being a decrease, compared with the preceding year, of 36.63 per 1,000, but an increase of 238.55 per 1,000, when compared with the average ratio of the last seventeen years—from the year 1884 when the improvement in the scale of diet commenced, to 1900. The average number of men sick daily was 1,602.37 which is in the ratio of 60.54 per 1,000 of force, being a decrease of 2.51 and an increase of 11.40 when compared with the preceding year and with the average of the last seventeen years respectively. The total number of cases recovered was 21,597, giving a ratio of 865.47 per 1,000 of cases, being a decrease of 57.21 and of 46.69 as compared with the last year and the average of the last seventeen years respectively. The number of deaths was 136, which gives a ratio of 5.45 per 1,000 of cases and exhibits an increase of 0.76, and a decrease of 6.00 in comparison with the previous year and the average of the last seventeen years respectively. The death rate per 1,000 of force was 5.14, which gives an increase of 0.55 when contrasted with the preceding year and a decrease of 2.92 in comparison with the average of the last seventeen years. Of the total number of deaths 97 died of disease, 9 from injury, 10 by drowning, and 20 by suicide. The death rate per 1,000 of force was 3.66 in the case of disease, 0.34 in that of injury, 0.38 in that of drowning, and 0.76 in that of suicide.

Of cases of general diseases, those of the respiratory system were very frequent, there having been during the year 1,928 cases, which gives a ratio of 72.84 per 1,000 of force. Nervous diseases were also common and there were 14 cases of kak'ke. Venereal diseases, however, headed the list, the total number of cases under this group amounted to 5,926. Diseases of the digestive system accounted for 5,025 cases.

The total number of injuries was 4,392. The ratio of mortality per 1,000 of force was 0.34.

The total number of persons vaccinated during the year was 9,157. The ratio of success was 41.79 per cent. and that of failure 58.21 per cent.

The entire report is a model of its kind, and is but another proof of the remarkable adaptability of the Japanese.

The Negro as a Patient.

Much has been written at one time or another concerning the negro, viewed from all standpoints. The problem of how to deal successfully with the negro question is one of such surpassing importance that all details in regard to the subject are of interest. There can be no doubt but that many of the ideas prevalent with respect to the black race in the United States are greatly lacking in accurate knowledge, and, therefore, any information which may be forthcoming from reliable sources should be welcomed.

Sometime ago, Dr. C. M. Brady of New Orleans read a paper before the local society entitled "The Negro as a Patient," in which he vividly described the unhappy condition of the negro from a medical point of view and suggested remedial measures. The writer summarized the chief causes of the excessive mortality among negroes as follows: (1) Neglect of the children through laziness and ignorance, especially in feeding children on fermented milk or solid food and considering the resulting illness due to teething, and therefore beneficial. (2) Insanitary surroundings, including poorly built dwellings and insufficient ventilation. Insufficient and poorly cooked food. (4) Insufficient clothing and covering and fire in winter. (5) Loss of rest. The average young negro does not obtain more than two-thirds the necessary amount of sleep. (6) Venereal excesses and untreated venereal diseases, syphilis. (7) Neglect in childbirth. (8) Drug and alcohol habits! Cocaine in wine is drunk to great excess among many of the young negroes of both sexes. (9) Failure to secure prompt medical attention. Failure to carry out medical directions as given.

This is the plan proposed by Dr. Brady to better the conditions of the negro race: (1) That from all negroes that work as laborers, farmers, clerks, mechanics, etc., from all those who earn wages in any legitimate manner, whose gross income from whatever source amounts individually to less than $900 a year, there be deducted 5 per cent. of their income, (2) That one salaried man be appointed in each parish to collect and disburse this fund and to have

supervision over all matters connected with the enforcement of the law. (3) That all employers and people who pay negroes for produce or articles created by them, deduct from their receipts the legal tax, according to this law, and that violations upon the part of either employer or employee be punished with a suitable penalty. (4) (*a*) With the funds thus collected it is suggested that there be employed in each parish such a number of suitable and competent physicians at a satisfactory compensation, that there should be no lack of capable and regular medical attention, all drugs and such necessities to be furnished free of cost to the patient. (*b*) Intelligent negro women of good moral character must be educated in nursing, and sent from house to house at the expense of the board to nurse all serious cases of illness. These women when not engaged in actual nursing must visit homes where there are young children and infants and teach the mother the proper methods of rearing them. They must perform all the usual duties of midwives in normal labor, and be instructed to call in the physician in all cases of labor that seem to be prolonged beyond the usual time. (*c*) In cases of disability from accident or disease, half wages be paid indefinitely until recovery, on the certificate of the physician. (*d*) A pension for old age be allowed to the heads of families when they are no longer able to earn a living. (*e*) A suitable contract to be made with a strong industrial insurance company to insure every individual practically without examination. The parish administrator to pay the dues monthly, or quarterly, by check to the home office, thus saving for the insurance company the heavy expense of writing and examining new business and the still heavier expense of the house-to-house collection of the dues for the old business. In this way a far more favorable rate of insurance can be granted by the company, with larger death benefits. (*f*) That the negroes be encouraged by the State Board to establish banks, factories, mills, and the like, and to furnish the labor and capital themselves. Dr. Brady suggested that a State board be created by the Legislature for the protection and advancement of the colored race, and that police powers be granted its members to enforce the above rules and regulations throughout the State of Louisiana.

In the discussion that followed the reading of Dr. Brady's paper, all the speakers, while agreeing that his scheme was impracticable, were unanimous in declaring that the condition in which the negroes of the South live was a distinct menace to their white neighbors, and was a matter which needed earnest attention.

Some Duties of the Army Surgeon.

The new "International Encyclopædia," which has just been issued, contains a brief article on military surgery, written by Major Louis L. Seaman, late Surgeon First U. S. Volunteer Engineers. The contribution in question presents certain phases of duty not appreciated by the military surgeon, and is of great interest throughout. The writer points out that the army surgeon must possess executive ability and a certain amount of military training, so that in time of action he can quickly organize his assistants and hospital corps, seeing that the wounded are brought promptly from the firing line to the first dressing station, which should be located at the nearest protected spot to the firing line. Here the wounded man can receive all necessary and immediate attention, promptitude in this respect being naturally a matter of the greatest moment. The problem of rapid transportation is also dealt with by the writer, and notice is drawn to the splendid results in the development of this feature which were attained in the war with Spain, by the hospital ships and fast railway train in charge of the surgeons of the American army, whereby many valuable lives were saved.

Perhaps, however, the most notable part of Major Seaman's article is that which treats of the duties of the surgeon when the army is not in action. It is at this period that he must show himself not only a capable surgeon, but "a keen sanitary engineer in the selection of camp sites, of camp drainage, of the location of latrines, in the inspection of all water supplies, the quality of food and its cooking, of the soldiers' clothing and his personal cleanliness. He must be an epidemiologist and a bacteriologist, as well as a student of dietetics and metabolism."

Major Seaman has made a special study of the diet best suited to the soldier when campaigning in tropical climates, and has written considerably on the subject. He is opposed to, what he terms, the iron-clad ration of the soldier, pointing out that this method of feeding has at times led to starvation or scurvy, or has proved an excitant to intestinal disease.

The remainder of the article contains valuable information and presents in condensed form the most salient features pertaining to military surgery.

Acute Ulcerative Endocarditis and Septicæmia Caused by Weichselbaum's Meningococcus.

A septicæmia due to Weichselbaum's meningococcus is believed to be of extreme rarity. Indeed, only in two instances has this microorganism been isolated from the circulating blood during life (Gwyn, Bulletin of Johns Hopkins University, June, 1899, and Salomon, *Berliner klinische Wochenschrift*, 1902, No. 45). Never has this diplococcus been proven to be the cause of a malignant endocarditis. For these reasons the case reported by Louis M. Warfield and John K. Walker (Bulletin of the Ayer Clinical Labratory of the Pennsylvania Hospital, October, 1903) is unique. The illness of the patient extended over a period of five weeks and terminated fatally. When first seen the patient was in a state of delirium with a temperature of 103° F. Shortly thereafter a systolic murmur transmitted to the axilla was discovered at the apex. The total leucocyte count was 11,100 and the Widal reaction was negative. The course of the fever throughout was irregular and septic in character. The total leucocyte count gradually increased. The Widal reaction remained persistently negative. Albumin and casts were present in the urine. No symptoms of meningitis were ever present. Ten days before death 6 c.c. of blood were taken from the general circulation. From this Weichselbaum's meningococcus was isolated. The same organisms were also obtained from cultures made at autopsy from the cardiac vegetations. In both of the cases above mentioned, in which this coccus was obtained from the circulating blood the clinical picture was one of meningitis complicated with inflammatory appearances in several joints. The symptomatology of the present case is so at variance with these that it possesses more than passing interest, since it shows that the result of an infection with the diplococcus intracellularis meningitis is not always the production of a meningitis, but that it may produce a septicæmia and malignant endocarditis, without involvement of the meninges. This at once opens up a new field for investigation in connection with the etiology of these conditions.

Cincinnati Death Rate.—During January 763 deaths were reported to the Cincinnati Department of Health, this being more than 50 per cent. higher than the average for the past fifteen years.

ANNUAL REPORT OF THE STATE CHARITIES AID ASSOCIATION TO THE STATE COMMISSION IN LUNACY.

The eleventh annual report of this commission has recently been published. The reception hospital bill is, perhaps, the most important measure mentioned in the report. This bill proposed to provide for the establishment of a reception hospital for the insane, through the joint action of the State and city of New York. The measure, however, failed to pass the Legislature, owing apparently to the amount of appropriation it carried. Another bill which did not receive the favorable consideration of the Legislature was also strongly disapproved by the association. This was the Bedford State Hospital Bill, framed with the view of establishing a State Hospital for the Insane in the buildings occupied by the New York State Reformatory for Women at Bedford. The association actively opposed the measure, which was introduced in the Legislature to centralize further the control of the State hospitals. The most salient features of the proposed amendment were that "the commission may appoint a treasurer, who shall act as such for all the State hospitals," and that contracts for staple articles of supplies may be entered into "by an agent appointed by the commission for that purpose." "The association felt that this would completely centralize the financial and business management of the State hospitals, and that, although the vast financial powers already vested in the State Commission in Lunacy were not sufficiently safeguarded, the changes provided for in the bill would remove several of the few remaining restraints upon the exercise of these powers."

The bill, notwithstanding the strenuous opposition of the association, was passed by both the Senate and the Assembly, but was vetoed by the Governor.

During the past fiscal year, 1903, the per capita rate of maintenance of the inmates of the New York State hospitals has been $172.55, an increase of nearly $11 over the rate of the previous year. "This increase," says the report, "is to a large extent due to the rise of prices, but is also due in some measure to a rise in the standard of care, especially in feeding and clothing the patients, and to the allowing of necessary and long-delayed repairs and improvements at the various institutions."

More buildings are greatly needed for the accommodation of the mentally deranged in New York State, as on October 1, 1903, there were in the fourteen State hospitals 2,666 patients in excess of the capacity of these institutions as last certified by the commission.

Although the building operations now going on will provide for the present overcrowding, no provision has been made for the future, and it is estimated that within the next three years there will be 3,300 patients for whom buildings must be made ready. This difficulty can be overcome in two ways: First, by enlarging the existing State hospitals, and second, by building new State hospitals. As to new hospitals the association thinks that these should be of two kinds—psychopathic, or reception hospitals in the large cities for the curative treatment of the acutely insane, and for the preventive treatment of incipient cases of insanity; and, large hospitals in the country on the colony plan, for both acute and chronic cases.

The report states that the diet in the New York State hospitals has been somewhat more satisfactory during the past year than during the previous year. With regard to the medical service of the aforesaid institutions, it is stated that an effort has been made to increase the efficiency of the medical work of the State hospitals by bringing them into closer touch with the Pathological Institute, established by the State Commission in Lunacy in New York City, and also by encouraging young men from the medical schools to enter the service as clinical assistants.

There has been, however, some difficulty in obtaining physicians to fill the vacancies which are steadily increasing. The reports of members of the State Charities Aid Association, who, during the fiscal year 1903, visited the various State hospitals throughout New York, are manifestly of great value and interest, but are too lengthy to deal with here. On the whole, the report for 1903 is encouraging, although, doubtless, many improvements might be introduced to the advantage of all concerned, into the management of New York State hospitals. It is, therefore, well that the "sins of omission and commission" which the association have detected should be sharply criticised, for reforms are brought about by such means.

BOOKS AS HARBORERS OF DISEASE.

The *New York Times* of February 8 has an article on the above subject, which is both well written and timely. This is preëminently the age of large free libraries, as it is also of microbes. The germ theory of disease has been evolved within a comparatively recent period, and hurtful microorganisms have been found to lurk in the most unsuspected places. Under these circumstances, then, it is by no means a cause for surprise that attention should be called to the menace to the general health afforded by the much-used public library and especially by the lending libraries. It is easy to conceive that epidemics of contagious and infectious disease may be quickly spread by the agency of contaminated books, and it is likewise hard to see how such occurrences can be entirely prevented. Books may be sterilized and disinfected, and yet may be full of noxious germs. The editorial in the *Times*, however, points out that the recent investigations of German microscopists concerning the number and variety of malevolent microorganisms found in colonies in the bindings and between the covers of books from the public libraries, are not, as is supposed by many, new discoveries. The fact has been known almost for as long a time as bacteriology itself. The multiplication of libraries of late has brought the danger resulting from the circulation of books more prominently before the public, and the question now is how to minimize this danger. Sterilization even when effective, is difficult to apply with success to books, and the problem presented does not lend itself easily to solution. Books, or at least some books, improve the mind, but when they, at the same time, injure the body, the reading public may truly be said to be on the horns of a dilemma.

Pittsburg's Unenviable Typhoid Record.—A comparative list of typhoid mortality of all cities in the United States of over 30,000 population for the years 1888–1891, inclusive, shows Pittsburg to be at the head of the list for that period, and Allegheny fourth. In the report of the joint commission in 1894 a table of typhoid-fever mortality for the five years, 1888–92, showed Allegheny at the head of the list and Pittsburg fourth. The two cities showing as great a mortality as that of Pittsburg in this table were Lowell and Lawrence, which have since applied the remedy. The census of 1880 showed the typhoid-fever rate per 10,000 population to be greater in Pittsburg than in any other city in the United States, Nashville being then a close second. These statistics leave no doubt of the fact that Pittsburg has for a quarter of a century suffered more from typhoid fever than any other city in the country.—*Pittsburg Despatch.*

News of the Week.

Our Minister to Korea.—The United States Minister to Korea is Dr. Horace Newton Allen, formerly of Delaware, Ohio. Dr. Allen, who is forty-five years old, is a graduate of the Ohio Wesleyan University, at Delaware, and of the Starling Medical College, in Columbus, and the Cincinnati Medical College. Twenty years ago, immediately upon his graduation from the Cincinnati Medical College, he was appointed by the Presbyterian Board of Missions as a medical missionary to Peking. He remained in China for a year and then went to Seoul. Here he gained favor with the court by his successful treatment of one of the princes. When the Korean legation was established here in 1888, Dr. Allen accompanied the officials to Washington and remained two years. He returned to this country again in 1893 to take charge of the Korean exhibit at the Chicago World's Fair. In 1894 he was made secretary of the United States Legation at Seoul and in 1897 was appointed minister.

Misfortune of the "Maryland Medical Journal."—We regret to learn that the February issue of this journal was destroyed in the Baltimore fire. It was devoted in large part to an account of the Tuberculosis Exposition, an elaborate and most valuable report of the exposition having been especially prepared for it.

Visit of Health Officers to Mexico.—The delegates from the boards of health of Alabama, Mississippi, Louisiana, and Texas have returned from their visit of inspection and conference in Mexico. The only formal proposition submitted by them to the Mexican health authorities was an agreement authorizing health inspectors of the four States, and also officials of the United States Public Health and Marine-Hospital Service to inspect any district in Mexico where yellow fever might exist or be suspected to exist for the purpose of investigation, and to determine the necessity of enforcing the quarantine regulations at the border. Dr. Licéaga said that the Supreme Board of Health of Mexico would take the proposition into consideration, and would make such recommendations as might seem warranted to their Government.

Possible Closure of the New York Eye and Ear Infirmary.—At a meeting of the Board of Directors of the New York Eye and Ear Infirmary, held February 10, a resolution was presented for consideration which suggests the closing of the hospital. The resolution fixes May 1 as the date for closing, this action being forced upon the directors by an increasing indebtedness. The expenses of the institution, it is stated, exceeded the receipts for the past year by $22,000, and the deficit of nearly $2,000 a month continues. The Infirmary has been in existence for eighty-four years.

A Gift to the Library of the Academy.—The Library of the New York Academy of Medicine has received, through the generosity of Drs. Alexander Lambert, Abraham Jacobi, Andrew H. Smith, Alfred Meyer, D. B. St. John Roosa, Robert W. Taylor, Walter B. James, Reginald H. Sayre, and Edward G. Janeway, a perfect set, in fine condition, of the "Acta Eruditorum," the first literary journal published in Germany. It enjoyed a long existence and great popularity. Otto Mencke began the publication of the journal in 1682. Its object was to give a faithful and particular account of books; and it was conducted on the same plan, even after a better taste in composition and greater independence were introduced into literary discussions in the French journals published in Holland. The German journal began, however, gradually to decline in value and in the number of its subscribers, particularly after 1754; and the irregularity of its appearance became at length so great that the last volume, that for 1776, was not published until 1782, exactly a century from the time when the journal was commenced. The whole set consists of 117 volumes in 4to, including the supplementary volumes and indices. Leibnitz, in this journal, first gave to the world his notions respecting the differential calculus. All the most important German medical articles of this period were published here, and also reviews of the medical works of this period.

Prevention and Suppression of Typhoid Fever.—Rules and regulations have been prepared by the Illinois State Board of Health relative to the prevention and suppression of typhoid fever. Copies of them have been sent to all the newspapers in the State, and to every county, township, village, and city health officer, and they will also be distributed among the people by the local health officers.

Red Cross Activity.—On the initiative of the Marquis de Vogue, President of the Naval and Military Volunteer Ambulance Society, the committee of the Red Cross in Paris met February 13, to take measures for affording assistance to the wounded of the two belligerent powers. From St. Petersburg it is reported that the American and English women there have started on the preparation of materials for the Red Cross Society with an enthusiasm equal to that of the Russian women engaged in the same work. Various committees effected a general organization last Sunday at a meeting held in the Anglo-American Church.

Typhoid Fever is prevailing epidemically in Watertown, N. Y. The source of infection is believed to be the city water supply derived from Black River, since the fever cases are widely scattered throughout the city, not a single street being without one or more cases. Inspectors are to be appointed to investigate the cause of the pollution of the river.

Report of the Chicago Pasteur Institute.—The director of this institute, Dr. A. Lagorio, reports that since the institute was opened, July 2, 1890, 2,026 patients have received the anti-hydrophobic treatment. Of these, 1,807 had been bitten by dogs, 76 by horses, 57 by cats, 19 by cows, 18 by skunks, 25 by other animals, and 22 were infected by hydrophobic human beings. Of individuals bitten by animals absolutely known to have been rabid, 982 were treated; of patients bitten by animals presumed to have been rabid because of symptoms of disease during life, 776 were treated, while 268 cases were cared for in which rabies was suspected. Only seven deaths were reported, a mortality of 0.34 per cent. Six individuals abandoned treatment, two of whom subsequently died from hydrophobia.

Ambulances for Japan.—Two hundred and thirty-six ambulances were shipped from Indianapolis last week for Japan. They were loaded in 118 flat cars, each car holding two ambulances.

College of Physicians of Philadelphia.—At a stated meeting, held February 3, Drs. John H. Musser and W. W. Keen presented a communication entitled "A Successful Operation for Perforating Ulcer of the Stomach in a Patient Past Seventy Years Old." The patient was a woman, who, for some time, had presented symptoms of gastric ulcer, with excessive acidity of the gastric juice. Symptoms of perforation developing, a diagnosis was agreed upon, and operation undertaken within five hours. The perforation was found at the pylorus, and by reason of the conditions present, a communication was estab-

lished at this point with the colon. A second case was referred to in which operation within twelve hours of the accident was followed by recovery. In both instances the result was favorably influenced by the fact that the patients had taken only albumin-water in advance of the accident, and the stomach was practically empty. On the other hand, the danger of underfeeding in cases of gastric ulcer was pointed out, on the ground that if the usually hyper-acid gastric juice is not made use of by food, it will proceed to digest the stomach itself and thus lead to peroration.

A Secretary of Public Health Indeed.—Congressman Baker of Brooklyn has introduced a freak bill providing for forty-five executive departments of the Government to look after all the needs and desires of American citizens. Of a piece with the rest is the section regarding the Secretary of Public Health, who is directed "to establish bureaus of healing, nursing, burying, and burning for the purpose of preventing and removing the diseases of mankind, as well as for removing pain wherever found, without charge, and to ascertain if possible and faithfully respect the desires of the people and their friends as to the disposition of their dead bodies."

New Cincinnati Hospital.—The Board of Medical Advisors of the Cincinnati Hospital received on February 2 the recommendations of the Medical Staff for the construction of the new hospital. They call for 1,000 beds, with 100 beds reserved for contagious diseases and also a nurses' home for 100 nurses. The recommendations were forwarded to the building Commissioners.

Compensation for Injured Laborers in Russia.—A law providing compulsory compensation for factory employees and miners in the case of all accidents has recently become effective in Russia. In the event of death an annuity is payable not only to widows and legitimate children, but to illegitimate children and to the mothers of such children and also to adopted children, the annuity to equal the wages of 260 days per annum, although the average of working days numbers only 220.

Crowded Hospitals.—The public hospitals in this city have been filled to overflowing with sufferers from pneumonia and other diseases commonly ascribed to exposure to inclement weather conditions. In many of the larger hospitals patients are lying on mattresses on the floors, and the smaller ones are obliged to refer many applicants for admission to other institutions.

The New York State Hospital for Tuberculosis, now in course of erection at Raybrook, will, it is believed, be ready for occupancy in April.

Dr. E. S. De Puy of Fruitvale, Cal., author of "The Courage of Ming Foo" and other works of fiction, is reported to have abandoned the practice of medicine for a literary career.

Bequests to Hospitals.—In the adjudication of the estate of the late Henry C. Cochran of Philadelphia bequests were allowed as follows: Pennsylvania Hospital, $10,000; Presbyterian Hospital and University of Pennsylvania, each $5,000; Gynecean Hospital, Polyclinic Hospital, Medico-Chirurgical Hospital, Home for Incurables, Sanitarium Association, each $1,000; Philadelphia Dispensary, Northern Dispensary, each $500.

Dr. Seymour Oppenheimer has been appointed laryngologist and otologist to the Mt. Sinai Hospital Dispensary.

Physicians Drowned at Manila.—A despatch from Manila reports that during a storm in the night of February 9 a native sailboat that was returning from Alabat Island with a party of Americans on board capsized and sank. Dr. H. Tetamore, a contact surgeon; Dr. J. Williams, a board of health inspector, stationed at Autimonan, and Burch and Grace McGrew, both teachers, from Auburn, Neb., were drowned.

American Nurses for the Japanese Army.—Dr. Anita Newcomb McGee, who organized a corps of nurses which did duty in Cuba in 1898, and afterward in the Philippines, has offered to fit out a nursing staff for service with the Japanese Army. This offer has been accepted by the Japanese Minister in Washington, and Dr. McGee will leave early in March with ten or twelve nurses to establish a field hospital with the army in Japan. Committees of women in various parts of the country will be formed to raise money for the support of the nurses. If the subscriptions warrant, other nurses will go.

District Appointments in Cincinnati.—Dr. J. W. Hall has been appointed District Physician for Cincinnati's Eighth Ward to replace Dr. C. W. Dawe resigned, and Dr. Frank C. King to replace Dr. J. T. McKibben in the Fourth Ward.

Measles Epidemics.—Measles is epidemic in Hope, Ind., and Findlay, Ohio, over two hundred cases having been reported in each of these places.

Typhoid Fever Decreasing in Cincinnati.—There has been a decided decrease in the number of typhoid-fever cases reported in Cincinnati for the past week, 50 new cases and 11 deaths as compared with 122 new cases and 15 deaths the preceding week.

The Masonic Home at St. Louis has drawn plans for the erection of a medical and surgical infirmary in connection with its building as a home for aged masons. The building will be one story, 100 x 50 feet, containing eight wards, operating room, office, and rooms for nurses. Dr. A. C. Leggat, attending physician to the Home, will have charge of the new addition.

An Insanitary Dairy.—Inability to reconstruct a dairy to conform to the city regulations of St. Louis has caused the proprietor to go out of business. An inspection of the dairy showed that the drainage was bad, the water supply unsatisfactory, and the stables and barns ill ventilated. Typhoid fever developed in some of the families who patronized the dairy. Strict orders were issued to put the grounds and buildings in perfect hygienic condition, but the proprietor said he was unable to do this and the dairy was therefore closed.

Pneumonia has prevailed in St. Louis in a peculiarly fatal form for the last ten days. Many have been attacked and not a few have succumbed to the disease. The climatic conditions seem to favor the development of pneumonia, the weather being cold and cloudy for several days, then followed by a warm season, which caused many people to disregard ordinary precautions. In the fatal cases the disease runs its course in from forty-eight hours to seventy-two hours.

Offers of Assistance Declined by the Japanese Red Cross.—Dr. Nicholas Senn, who offered his services to the Red Cross Society of Japan has received a reply from Baron Hashimoto to the effect that the organization has not the power to accept the proffer of assistance. Dr. Senn states in explanation that the Japanese Red Cross Society is one of the best in the world and is able to take care of all wounded for many months to come.

Obituary Notes.—Dr. EMILE A. DE SCHWEINITZ, chief of the biochemic division of the Bureau of Animal Industry of the Agricultural Department and dean of the Medical Department of Columbia University, died of uræmia at his home in Washington, February 15, in the thirty-eighth year of his age. He was born in Salem, N. C., was educated in the Nazareth

Hall, Pa., High School and the Moravian College of Bethlehem, Pa., and was graduated from the University of North Carolina in 1882, receiving the degree of Doctor of Philosophy at Göttingen, Germany, in 1886, and Doctor of Medicine from the Columbian University in 1894. He was United States delegate to the Fourth International Congress on Tuberculosis at Paris in 1898, and in Berlin the following year. He held the same appointment to the International Medical Congress and Congress for Hygiene at Paris in 1900. He was a member of the International Applied Chemical and Biological Society, the German Chemical Society, the French Society of Pure Chemistry, and practically every American scientific society of importance. Although a comparatively young man, Dr. De Schweinitz had won an enviable reputation as a bacteriologist. He was an earnest scholar, an investigator of much originality, and a prolific writer on bacteriology, hygiene, and orrhotherapy. Tuberculosis was seemingly his favorite subject of study.

Dr. EDWARD C. RUNGE of St. Louis died at his home on February 9. He was ill only a few days succumbing to an attack of pneumonia. He was born in St. Petersburg in 1857 and received his education at the University of St. Petersburg. He was graduated in Medicine from the St. Louis Medical College in 1891. In 1895 he was appointed Superintendent of the St. Louis Insane Asylum and was retained in this position through the administration of three mayors of the city. A little more than one month ago he retired from his position and entered private practice.

Dr. HENRY LYLE SMITH of Hudson, N. Y., died February 11, at his home in that city, at the age of sixty years. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1864, and began practice in Hudson in 1867. He was a member of the Medical Society of the County of Columbia, of the Medical Society of tye State of New York, of the New York State Medical Association, and of the Society of the Alumni of Bellevue Hospital.

Dr. MAXIMILIAN G. RAEFLE, who served in the Medical Corps of the navy in the Civil War and who was for several years deputy coroner in this city, died of apoplexy on February 12. Dr. Raefle was born in Baden, Germany, in 1836, and was graduated from the Humboldt Medical College, St. Louis, in 1861. He served under Admirals Farragut and Porter in the Civil War.

Dr. JOHN MERCER ADLER died of apoplexy at his home in Devon, a suburb of Philadelphia, on February 12, at the age of seventy-six years. He was born in Georgetown, D. C., and was educated in Georgetown College and Princeton University. Studying medicine at Columbia University, he was graduated with the class of 1847. Immediately after this he went to Colon, being connected with the Panama Railroad. Three years later he returned to this country, going to Davenport, Iowa., as chief physician of the Military Hospital there, and was in charge during the entire Civil War. With the close of the war he went to Philadelphia.

Dr. CHARLES AUGUSTUS WHEELER of Leominster, Mass., died in the Massachusetts General Hospital, Boston, on February 11. He was born in Fitchburg in 1836 and received his medical degree in 1857. He served in the medical corps of the Union Army during the Civil War.

Dr. CHARLES W. DODD of Cincinnati died of apoplexy at his home in Mt. Auburn, on February 7. He was born in Cincinnati, forty-four years ago, and was graduated from the Medical Department of the University of Michigan in the class of 1884.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BART'S; THE CITY MEETING—OUT-PATIENT ABUSE—MOORFIELDS, QUESTION OF FINANCIAL MANAGEMENT—INSTITUTE OF MEDICAL SCIENCES—RESEARCH FUND FOR THE HOSPITAL FOR PARALYSIS—PICRIC ACID POISONING.

LONDON, January 29, 1904.

THE city magnates assembled in great force on Tuesday, filling the Egyptian Hall of the Mansion House (many, indeed, being obliged to content themselves with standing room) in response to the invitation of the Lord Mayor to meet in furtherance of the appeal for St. Bartholomew's Hospital. The great hospital is within the city and the city is very proud of its noble charity. The appeal to the wealth of the city was, therefore, sure of hearty support. The treasurer of the hospital, Sir Trevor Lawrence, son of the great Bart's surgeon, was the first speaker. He held that the question of the site was thoroughly thrashed out by the Mansion House Committee last year—which was practically unanimous in favor of retaining the present position. It was a rare circumstance for a great charity to occupy the same site for 800 years. It had been suggested to divide the hospital, but that would involve many difficulties and the destruction of the school. This latter was the next most important thing to the treatment of the patients. Sir Trevor further said the value of the site had been greatly exaggerated. The circumstances were not the same as when the Christ's Hospital land was bought; then two would-be purchasers were in the field—now they would have to be compulsory sellers of the present site and compulsory buyers of another. On the present site seven million patients had been treated in the last fifty years. The present buildings were erected 150 years ago, and though altered as required from time to time, were rather antiquated. Certain departments required immediate attention. Six new blocks of wards, an isolation block, and other buildings were wanted. It was estimated that £438,000 would give them an entire new hospital. The income for the last ten years averaged £67,000 per annum. But the purchase of the additional land, that had been made, so reduced the capital that the loss of income would be about £6,000.

The Bishop of London moved a resolution approving the decision to reconstruct the hospital on its ancient city site, and said he was following the best traditions of his office, for a prebendary of St. Paul's founded the hospital, a bishop of London found the land, and the lord mayors and bishops had worked together for it for 800 years. As to the site he was content to take the verdict of the sixteen honest men who went into that question. He could imagine a plausible plea for removing St. Paul's on the mere ground of the value of the site.

Sir Wm. Church (president R. C. P.), who had been connected with the hospital for forty years, seconded the resolution and spoke of the 40,000 workers who came into its neighborhood daily, among whom accidents were sure to occur. So the heavy city traffic was another cause of the influx of patients.

Mr. Tweedie (president R. P. S.) supported, asking that the historic and sentimental interest in the hospital should be remembered, and what would not New York give to have in her borders such an institution, in which Harvey and Hunter worked?

Dr. Gee also supported, and declared antiquity did not mean decrepitude, but in this case was a sign of perennial youth.

The resolution was carried with only three dissentients and then Mr. Alban Gibbs, M.P., moved one commending the appeal, which is the only one for 150 years, to the public. As to the city, he said it was not a charity, but a duty to give.

The master of the Mercers' Company, who seconded said one of his predecessors, Sir Richard Whittington helped to restore the hospital, and 150 years later Sir R Gresham, when Lord Mayor, petitioned Henry VIII, who gave back the charter and part of the estates. His court supported the present movement, and the city guilds could not use their wealth better.

The chief rabbi, Sir Hart Dyke. M. P., and Mr. Bowlby supported, in appropriate speeches, and the resolution was carried with three dissentients.

Sir W. Treloar said the committee had already received money or promise, to the extent of £40,000, including £1,000 from the Queen. A vote of thanks to the Lord Mayor concluded the proceedings.

The question of hospital abuse is raised afresh by the appeal, for it has been put forward that 150,000 out-patients are attended in the year. But who does not know that this figure does not represent the very poor, but wage-earning people who could well afford to pay the

moderate charges of the struggling young general practitioner? This boast of great numbers is very misleading.

Appeals for funds for our hospitals are always being made, but at the present time they seem more numerous as well as more urgent, than usual. It seems unfortunate that so many should be made simultaneously, for the most generous of contributors can scarcely comply with all at once, and there is great difficulty in discriminating. The question of hospital abuse mentioned just now will become more urgent and the public will be obliged to consider it.

Among the hospitals in urgent need let me to-day select the Royal London Ophthalmic, more commonly known as Moorfields, though no longer situated in that locality.

When it was proposed to buy the present site in the City Road and build the present hospital, I pointed out the danger of the financial difficulty which is now pressing on the management. It seemed to me an extravagant plan to build on a site, at a rental of £1,210 per annum, to which rates are to be added of nearly £1,000 more. The old Moorfields was only rated at £55, and those who thought rating authorities would give up their claim, must have been strangely optimistic. The managers, however, were infatuated, and are now landed in a heavy debt. The generosity of the public will not be wanting, but the example of recklessness should serve as a warning to other managers. The King's Hospital Fund, in its last report, says "this hospital should receive more support from the public," and as regards the current expenses, I cordially endorse the statement. At the same time, the object lesson should not be lost sight of. Old "Moorfields" was long the Mecca of ophthalmologists. They flocked to it from all countries, and the staff is still carrying on the traditions of this great special school. This is its centenary year, and so many of your readers are familiar with its work they may be interested to learn that it was established in Charterhouse Square chiefly to meet the needs of the sufferers from ophthalmia in the Egyptian campaign. In 1821 it was removed to Moorfields, and the present new buildings were opened in 1899. It has special claims on the public, and I hope they will soon be met, but none the less its difficulties should be a warning to managers of other charities, who are far too ready to rush into debt. In fact this propensity of hospital managers is a crying evil.

The appeal of the Senate of the University of London for funds to build and endow an institute of medical sciences has received the support of the general hospitals in the form of a letter from the several chairmen or treasurers addressed to the chancellor of the university.

An appeal has been issued by the National Hospital for the paralyzed and epileptic for contributions toward establishing a research fund. So many visitors from your side have seen the work carried on at this hospital that I am sure they will be glad to hear that the appeal is successful.

Picric acid has been so freely used in burns that it may be well to remember that symptoms of poisoning may be produced. Two such cases were recorded by Dr. J. S. Rose in the *Scottish Medical and Surgical Journal* for December. An ointment was employed of the strength of half a dram to the ounce—certainly rather strong. A solution of 1 per cent. is more commonly prescribed, and some have used the dry powder.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PROVINCIAL HOSPITALS—COMPARATIVE MORTALITY AMONG THE RESIDENTS OF MANILA—SPECIAL INSTRUCTION FOR MEMBERS OF PROVINCIAL BOARDS OF HEALTH.

MANILA, December 31, 1903.

The Board of Health is about to establish and operate twelve hospitals in the provinces, to be located at points throughout the archipelago, which are centers of populous districts, and on ready lines of communication. Where practicable, suitable buildings will be rented for hospital purposes, and this can be done in about two-thirds the cases. In the remainder it is proposed to construct modern hospitals on the pavilion plan. Each hospital will have of fifty beds' capacity, and have facilities for the treatment of both whites and Filipinos. There will be an American and Filipino physician assigned to each hospital, with one or more white trained nurses and a further personnel of Filipinos. The hospitals will be fully equipped and modern in every way. They will be a great blessing to Americans in the provinces, as well as to the Filipinos, who are now in many places unable to secure proper medical attendance or hospital treatment. To the shame of Spain, there was not a single hospital in the Philippine Islands outside of Manila, before the arrival of the Americans. The friars, who absorbed such a vast proportion of the wealth of the islands, made little effort to return a part of it to the class from which it was derived, by instituting hospitals and dispensaries in the name of humanity. In fact, the attitude of the Spanish Government was to ignore the needs of the Filipinos, and of the Spanish friars to belittle modern medicine, and teach that disease and death was a punishment from heaven, only to be averted by prayer. The new hospitals will be free to the poor, but a small charge will be made to government officials and others able to pay for the same. It is proposed to operate a dispensary and out-patient department in connection with each hospital, under the native resident hospital physician, while it is intended that the American physician shall also act as the immediate local agent of the insular board of health and supervise sanitary work by the provincial health boards in the several provinces assigned as his hospital district. Such immediate supervision over provincial sanitary work is much needed in order to properly direct the efforts of the provincial sanitary authorities, and prevent them from falling into the official lethargy but too common to the natives of these islands. The general organization and function of the provincial hospitals in the provinces will be similar to those operated in Formosa, where the Japanese have ten such hospitals, one of as much as 170 beds' capacity.

The report of the Board of Health for the month of October shows that the rate of mortality among the Filipinos in the city of Manila was nearly five times greater, and among the Chinese two and one-half times greater, than the death rate for the combined American and European population of the city. These facts reflect the value of the more hygienic modes of life of the latter class. Inoculation of the Chinese population against plague was resumed during the month, with the purpose of completing the immunization of this class of the population by December 31. A list of every house in which plague has ever occurred has been prepared, and, together with those in their immediate vicinity, reinspected and ordered put in proper sanitary condition before the same date. Rat-catchers have been directed to devote special effort toward the extermination of rats in such houses and their vicinity, and a total of 21,928 rats were thus destroyed during the month. The sanitary situation in the city of Cebu being unsatisfactory, the insular board of health took all health matters out of the hands of the local board of health and assumed direct control of all sanitary matters through a committee appointed for the purpose. For the purpose of promoting greater efficiency on the part of provincial and municipal sanitary officials, more rigorous inspection of their work was ordered, and efficiency records were established for securing better knowledge respecting the efficiency, aptitude, attention to duty, personal habits and fitness for promotion of these officials. The sanitary authorities have also established a course of instruction, by object lesson, in Manila, for the presidents of provincial boards of health throughout the islands. Few of these men have been outside of the Philippine islands, and they have had no opportunity to familiarize themselves by practical experience with modern methods of sanitary procedure. The course of instruction is wholly practical and covers a period of four weeks. Small classes are ordered up every month, and it is expected that in six months all the forty provincial health officers will have completed the course of instruction. The course includes six days as assistant at a district sanitary station, observing its general management, house, and food inspection, disinfection, plague inoculation, rat-catching, and the treatment of plague and cholera houses, the service of sanitary orders, diagnosis and transportation of infectious cases. Three days are spent in instruction in port quarantine and ship disinfection, under the chief quarantine officer. Two days are employed with the inspector of plumbing and the chief of the pail conservancy system, observing the methods and appliances in use for the sanitary reception and disposal of excreta. Instruction is given for two days by the veterinary surgeon in clinical and post-mortem diagnosis of the epidemic diseases of live stock, and the examination of animals and carcasses at the abattoir. Two days are spent at the Serum Laboratory observing the methods of preparing serums and vaccine virus, also of inoculating against rinderpest, and the use of fungus in destroying locusts. One day is spent with the city vaccinators, observing methods of vaccinating and maintenance of records. Six days are spent at the San Lazaro hospitals, observing the management and equipment of the plague, cholera, smallpox, leper, women's morgue, crematory, and steam disinfecting departments; the treatment of the sick, and the method of making post-mortem examinations and disposal of the dead. Finally, two days are spent in the office of the secretary of the Board of Health, to observe the method of keeping records, the calculation of vital statistics and the preparation and use of reports; also to be present at meetings of the the Board of Health and note methods of procedure.

The officials under instruction are expected to profit as far as possible by the opportunities afforded under the

above course, are required to take notes, and will be called upon to render a report at the conclusion of the course to show the professional benefit derived therefrom. The industry, zeal, and aptitude of each man will also be reported upon and entered in his official record for consideration in connection with future retention or promotion. Travelling expenses to and from Manila are allowed, and per diems of two dollars authorized for expenses for each day while under instruction.

THE EXAMINATION OF STOOLS FOR SOLID BODIES.

To the Editor of the Medical Record:

Sir: A few weeks ago Dr. Howard Lilienthal described, in the Medical Record, a "Simple method for examining the stools for gallstones and other solid bodies." His method is a very good one, but I do not suppose he will object to hearing of another and more simple manner of "doing a dirty job" neatly.

The plan I have used for a number of years is the following, and its simplicity will commend it to physician, nurse, and patient:

Take an ordinary flour-sifter with handle and wire crank, such as may be obtained at any housefurnishing store for fifteen cents. When needed, the sifter may be placed in a chamber commode, or the bowl of a water-closet, the passage being deposited in it. It can then be set into a chamber and taken to a hopper, or where water can be allowed to run through it, at the same time the crank is turned gently. This quickly washes away the débris from the scybala, leaving only hardened material such as gallstones or foreign matter in the sifter.

Charles V. Cross.

916 Market Street, San Francisco.

SHALL THE GENERAL PRACTITIONER DIVIDE FEES WITH THE CONSULTANT?

To the Editor of the Medical Record:

Sir: The question as to whether or not the general practitioner should divide fees with the consultant presents many matters for consideration. As an ordinary physician who frequently has consultations with specialists, I may be privileged to give my point of view from the practical side of experience. I venture to say that the principle of reciprocal money dealings between the parties concerned is wrong, no matter how it may be explained. In every case in which a pecuniary consideration is entertained the judgment of the interested individual is always biassed. It is the price to be paid for the alleged favor. Thus the most competent man is not always selected. It implies collusion between "grafters." It is easy to see that the patient trusting in the impartial judgment of the man on whom he places the responsibility of deciding the issue does not get fair play. It is not a question of actual fitness to perform an operation, but one in which the highest bidder or the most liberal doler controls the issue. I have always contended that the giving and taking of divided fees is radically wrong for both parties. If the practitioner takes his commission he is either depriving the expert of a fee which the patient is willing to pay for such special service or is loading an unnecessary burden on the payee by an extra item on the bill, the real purpose of which is concealed. This makes the family doctor descend virtually to the position of a mere drummer for his expert friend, while the latter is placed in the still more humiliating position of accepting money under false pretenses.

It has been asked how the practitioner is to be compensated for the temporary loss of his patient? As regards the special work to be performed he has no right to be considered in the matter. He is simply incompetent to perform the work which another can do for him, and for the time being loses all extra pecuniary claim either on the consultant or patient. The bargain from a strictly business consideration is between the two principals concerned, the operator and his subject.

But what about the prestige of the family doctor? Certainly, all round man as he may be, he cannot be expected to be an expert in all branches. It should be no lowering to his pride to say to his patient that a particular case requires special treatment. Far from lowering himself in the eyes of the patient he elevates himself to the position of a trusted adviser and a man of good judgment. The patient is more than ever inclined to trust to his opinion in other like emergencies and feels relatively safer with a man who knows his limit than one who always knows it all. The specialist at work is merely in temporary command. Does any one mistrust the captain of an ocean liner because he signals for a shore pilot? On the contrary such an act always stamps the captain as a safe man in any extra emergency. No dignity is ever sacrificed, as each man has his own place for the time being.

There is often trouble, I admit, in having these relati positions clearly defined. Some of the specialists ha on too long, while some feel as if they own the patient long as his nose, throat, and eyes last. They thus put t client on a new tack, and the female, especially on her o account, may sneak to the new office for treatment of h "womb complaint." This, of course, cannot be help when a dishonorable expert gets into a case. But I ta it that this is an exception rather than a rule. At pres there is no known remedy to make a silk purse out o pig's ear. The condition is wholly one of profit and lo and must be so accepted when the principles of me business and sharp practice govern certain individu Specialist and practitioner each have their place, and they keep them, there need be no reason for any m understanding. They can work legitimately into e others hands by maintaining proper reciprocal relati without mere money from one to the other coming i the transaction. There need be no mixed business i the consideration. The specialist comes in for spec work, and when he has done it he should retire at t earliest possible moment. In any necessary after-tre ment the practitioner should be his right-hand man, a should represent the patient as general counsel. These distinct functions, which should be separately paid for the patient without the necessity of dividing a gene fee. The same rule should be applied to all operati in which the physician assists either directly or indirect Further than this, the specialist can often recomme the practitioner to such patients as may require gene treatment, and thus repay courtesies in a becoming a acceptable manner. If such understandings could ex there would be no need of a back-door "graft" syste which is a disgrace to an honorable profession.

Vindex.

To the Editor of the Medical Record:

Sir: I am one of the large army of hard-working prac tioners whose practice consists of obstetrics, surgery, ve ereal, and children's diseases. But then I have a la family to support, and my expense equals my income. have a life insurance which must be kept up, and this really all I should leave if I die. With me, as with m of my fellow workers, bread and butter comes first. Th high-toned, independent, know-everything chaps, specialists, seem to think, as does your correspond that it is a crime to divide the fee with the general pr titioner. Do we not lower ourselves for the time bei both in the eyes of the patient and surely in the eyes the specialist? Are we not frequently told by the fa that Dr. So-and-so, a specialist, or Professor So-and- will see mother at 4.30 P.M.? Has it not happened others as it has happened to me, that I had a woman labor pains just at the time appointed, and rather th be discourteous, hurriedly sent for my friend across t street to look after my case, and the result was that t family discharged me for neglecting to serve them wh they most needed me. I confess I do ask for and receive part of the consultant's fee. Whose business this? Who regulates my own fees? If I think my co sultation is worth only fifty cents in the office, this do not concern the medical societies or the code of ethi Are there not hundreds of men who attend families f two and three dollars a year? Does this mean that th can live on such paltry incomes? Dr. Robert T. Mor is very wrong when he says: "That if the specialist charg a fee and gives part of it to the physician as a commiss the transaction is in the nature of trade." Evidently I Morris has a great deal to learn concerning the rank a file of the profession, or else he must have an exclusi consultation practice.

One word regarding the interesting letter of Dr. Per Dickie. This gentleman is broadminded and liberal, a surely is the man who sees the point. He says: "It the duty of the specialist to reimburse the general pra titioner, not only for losing the patient but for the sac fice of the patient's confidence." I wish that some o of us would have the backbone to have this statement Dr. Dickie's put in the form of a resolution and sent the medical societies of the State, as I am sure that t voice of the profession would answer "yea" to his not sentiments.

A General Practitioner.

Addition to Presbyterian Hospital of Chicago. Directors of this institution are considering plans f the construction of additions to the hospital. The will include a surgical pavilion and a new out-patie dispensary for the poor. Part of the $500,000 r quired for these additions has already been pledg

SUPPRESSION OF MALARIA ON THE ISTHMUS.

To the Editor of the Medical Record:

: Do you ever listen to suggestions from laymen? ave been reading the article in your issue of Febru- 6 on "Mosquito Extermination an Engineering blem." It seems to me that, so far as the extinction malarial germs from the line of the Panama Canal is cerned, the problem is one which can be solved at an ense immeasurably less than that which would be uired in treating it as an engineering question, pro- d the authorities in charge of the work are able and ng to treat it for a short time in a drastic manner.

s I understand the well-proved theories regarding quitos and malaria, the following facts are established: Malaria is communicated in no other way than by anopheles. (2) The life of an anopheles does not ed ninety days. (3) The fact that a human being malaria in his system can be ascertained positively a microscopical examination of his blood.

seems to stand to reason that if a district infected malaria—that is infested by anopheles—could be utely depopulated for ninety days the malady ld be absolutely exterminated over that district, could be reintroduced only by the coming into it of an beings having malaria. Undoubtedly if the gov- nent undertakes the construction of the canal it will repared to exercise to the full the authority granted e pending treaty. It would, of course, be arbitrary ause a certain amount of hardship to take the steps sary to carry out the suggestion I am endeavoring ake. But considering that the cost of completing construction of the canal is approximately $150- 000, and considering also that the cost of exterminat- the anopheles by almost impossible processes of nage would be enormous, considering also the im- se expense involved by the establishment of hos- ls and other sanitary measures—does the suggestion wild that the government should absolutely de- ate the canal strip during the time necessary to rminate the anopheles in this way? Of course the sit by rail must be maintained, but it would not be cult to take all the precautions necessary to prevent spread of malaria during the ninety-day period. example, it should be provided that all the persons ged in operating the railway should be carefully ined and their freedom from malaria fully proved. the same rule should be applied to the station men others necessarily employed along the route, and they should be required to remain secluded in mos- o-proof houses during all the nights. The passage ains would probably not involve any risk. They ld run in the day time only, and the anopheles is stomed to feed on human beings in the night only. e are other measures which occur to me but which I not mention, by the use of which, with those already ested, the work of exterminating the mosquitos capable nveying the disease could be made thorough and ect. The further steps would be by no means diffi- They need perhaps be nothing more than an exami- on of the blood of all the workmen imported before should be allowed to enter the zone for the purpose gaging in the excavation. Edward Stanwood.

ODE OF INFECTION OF TUBERCULOSIS.

To the Editor of the Medical Record:

As bearing on the atrium of tuberculosis for man, ther generally by the alimentary or respiratory tract, following facts may be of interest:

Havana up to 1901 (I am not familiar with its con- ons since) tuberculosis was prevalent. I find for the years (from 1890 to 1894) preceding the war the hs from tuberculosis were 1,661, 1,573, 1,531, 1,331, 1,366 respectively, the average being 1,492 per annum. average total mortality for these years was 7,058, ing the deaths from tuberculosis over twenty-one per . of the total mortality. The population of the city ng this time was about 200,000. These years are cted because during the years of the war and those diately following the social and sanitary conditions e so changed that they were not average years, and statistics for such years would be misleading—for ance, over 3,200 deaths from tuberculosis are reported 898. The years selected are chosen as being average s.

ow there is not one drop of cow's milk unboiled used lavana—the infinitesimal quantity of asses milk used d not be considered. Milk then can be eliminated as ource of tuberculosis. Butter is not used, and only a d and very mature cheese and to a very small extent. The other animal food before the American Intervention was: (1) Codfish; (2) jerked beef (tasajo) from the Argentine Pampas; (3) beef from central and eastern Cuba; (4) hog products of the United States to a very small extent. Three-fourths of the animal food, however, was codfish and tasajo, both of which should be absolutely free from tuberculosis bacilli. The same should be nearly true of Cuban beef, as it was never stalled—the cattle being half wild. In addition, meat in Cuba is eaten well-cooked, usually in a stew. It is *never* eaten raw.

It would seem then that the introduction of tuberculosis by way of the alimentary by animal products, should not occur in Havana, and yet the figures above show the disease to have been decidedly prevalent—above the average for towns of its size. It may be noted here that during the five years taken, the deaths from tuberculosis in Havana averaged nearly seven times as many as those from yellow fever, yet we have always spoken of Havana as "scourged with yellow fever," while the prevalence of tuberculosis there has attracted little comment.

Some Conclusions Based on a Study of One Hundred and Thirty-four Cases of Calculus in the Ureter.—Benjamin Tenney sums up his paper as follows: Intermittent pain on one side, with varying amounts of red blood in the urine, are constant symptoms of stone in the ureter. Though the best means of locating stones, the *x*-ray cannot yet give evidence sufficient in itself to warrant us in operating or refusing to operate on certain cases. If a calculus starts from kidney to bladder, it is likely to catch within an inch of one of three places, all of which are accessible to the surgeon through extraperitoneal openings. A single calculus is the rule, but the exception occurs, according to these cases, about once in eight times. The opening in the ureter or kidney pelvis for removal of the calculus should be sutured if possible. Both sorts of suture materials have been used with equally good results, and wounds in both locations apparently heal equally well. The recovery is only delayed if sutures are not used. A calculus in the ureter is a menace not only to health but to life, and its removal is an operation of low mortality, provided it is undertaken before secondary changes appear in the kidneys. The writer concludes his article with a valuable chart of cases.

Decapsulation of the Kidneys.—Edward Reynolds presents the following conclusions which he believes rather tentative: (1) We must admit that our present knowledge of the pathological physiology of renal disease is still defective, but we are justified in believing that nephritis has, as a rule, an infective origin, and probably that the defective renal drainage, due to swelling of the organ within a rigid capsule, plays a part in maintaining the disease. (2) That the cases in which general uræmic symptoms are more prominent than the physical signs obtained on the examination of the urine are unpromising cases for operation. (3) That where the urinary signs and constitutional depression outweigh the distinctly uræmic general symptoms, we may regard the cases as favorable for operation. (4) That where one kidney is mainly or predominatingly affected, a unilateral operation upon that kidney offers an excellent chance of prolonged improvement in health, if not, indeed of ultimate cure. (5) In women, in whom ureteral catheterization involves little trauma and less risk, all cases of chronic nephritis should be subjected to ureteral catheterization and the unilateral ones selected for operation. The writer believes that the ureteral catheter furnishes the only method of segregation of the urine which can as yet be regarded as definite. In women the use of the ureteral catheter is exceedingly easy, and the writer thinks may fairly be said to be non-injurious. In a large series of cases he has never seen an untoward symptom.

Journal of the American Medical Association, Feb. 13, 1904.

New Aspects of Yellow Fever Etiology.—C. J. Finlay reviews the experimental findings of the last three years. It is generally believed that from ten to twelve days must elapse between the bite of the stegomyia of the yellow-fever patient and the inability to inoculate another patient. During this time a series of transformations goes on in the body of the infected mosquito. These are presumably as follows: (*a*) Introduction of young sporozoits sucked up with the blood of the patient. (*b*) Growth of the sporozoits to adult age. (*c*) Formation of schizonts and merozoits. (*d*) Formation of gametes. While in the body of the non-immune, counting from the moment

of his inoculation by the infected stegomyia, the following stages are likely to take place during the period of incubation: (*a*) Localization of the gametes in appropriate sites. (*b*) Fecundation of the macrogametes by the microgametes of the yellow-fever germ. (*c*) Formation of the oökinet and development of the oöcyst in appropriate cells (endothelial)? (*d*) Discharge of free sporozoits of yellow fever into the circulating blood (perhaps too small to be recognized with the microscope). (*e*) Development of the toxæmic symptoms characteristic of the invasion of yellow fever in the inoculated non-immune.

A Consideration of the Neuroses of Status Lymphaticus.—These neuroses are enumerated by A. P. Ohlmacher, who places at the top of the list the sudden death occurring in victims of lymphatism from a wide variety of causes. Secondly the author names infantile eclampsia. Some of the children who have died in the convulsions of teething have been found to have had enlarged thymus and lymph-adenoid hyperplasia. A third neurosis is glottic spasm, and infantile tetany may be mentioned under this head. Finally there is at least a frequent coincidence of idiopathic epilepsy and the status lymphaticus. All cases of the latter diathesis are liable to sudden œdemas, and these may sometimes be the immediate cause of death or may lead onto the various neuroses above enumerated. According to this view, the clinical phenomena would depend on the extent and location of the intracranial œdema, or, in other words, on the portion of the encephalon particularly subjected to pressure. In event of compression of the external portion of the cerebrum various convulsive disorders of the motor apparatus are provoked; when the balance of pressure becomes so distributed as to raise the intracerebral pressure other severer symptoms occur, ending in case of sufficient pressure on the floor of the fourth ventricle in sudden respiratory or cardiac failure.

The Present Status of the Uric Acid Question.—The views of W. Baumgarten are expressed in the following summary: The source of uric acid in mammals lies in the nucleins and their decomposition products, the purin bases. The uric acid eliminated in the urine arises partly from the nucleins and purin bases due to the breaking down of cell nuclei in the body itself, that is, the endogenous uric acid; and partly from the nucleins and purin bases contained in the food, the exogenous uric acid. The amount of endogenous uric acid excreted in twenty-four hours is the minimum which the individual normally excretes; it does not change in quantity, though it varies with individuals; it is influenced only by the mode of life, but in no way by the quantity or character of the constituents of food which do not belong to the group of nucleins and purin bases. The exogenous uric acid is always an addition to the endogenous uric acid, and depends in amount entirely on the quantity of certain purin bases contained in the food. Of the free purin bases only the oxypurins, hypoxanthin and xanthin, increase the uric acid elimination; of the bound bases both oxypurins and aminopurins increase the uric acid; the methylated purin bases do not effect the uric acid elimination, but increase the purin bases in the urine. Of the oxypurins, both bound and free, one-half is excreted in man as uric acid; of the bound aminopurins, some appear one-half, some one-fourth as uric acid. The fraction is in each case independent of the individual, and is practically constant. Uric acid is not an end product of metabolism, but is intermediary between the purin bases and some lower oxidation product which has lost the purin characteristics. This product may possibly be urea, but this is certainly unproven in man and only probably in lower animals. In the carnivora allantoin, in the herbivora glycocol, forms a large portion of the recoverable oxidation products of uric acid.

Medical News, February 13, 1904.

Enlargement of the Phalanges in Rickets: A Report of Two Cases.—Jacob Sobel reports two cases of rickets with enlarged phalanges. In the first case, the first, second, and third phalanges of all the fingers of both hands, and both phalanges of the thumbs were thickened. There was no pain or tenderness on pressure, no œdema of the skin or enlargement of the joints. The phalanges of all the toes showed a palpable thickening, though to a far less degree than those of the fingers. This thickening affected the shaft, and more particularly the middle, rather than the epiphyseal ends. The enlargement of the three middle fingers was more marked than that of the thumb or little finger. This first child was a boy. The sister showed thickening of the phalanges of the fingers and toes, though it was less marked than in the former case. The rachitic manifestations were very marked in both of these cases. The writer has seen, however, several cases of rickets of not unusual severity in which some phalangeal thickening existed. He believes that this condition is very frequently overlooked, owing to lack of attention to the hands and feet.

Treatment of Pneumonia.—Delancey Rochester states that the recognition of the fact that pneumonia is not a local disease of the lungs but an acute infectious fever with its most pronounced anatomical lesions in the lung, gives a basis for the rational treatment of the disease. The writer has recently had an experience that convinces him of the utter valuelessness of the antipneumococcic sera that are on the market, and he believes that until a true antitoxin for pneumonia is obtained, such as we have for diphtheria, the best results will come from recognizing the essentially toxic nature of the disease and treating it along the eliminative supporting lines which he summarizes as follows: (1) The sustaining of the metabolic processes of the individual by the administration of easily digested or predigested foods in small quantities at stated intervals, the administration of large amounts of pure water for eliminative purposes and the administration of oxygen gas by inhalation whenever the absorbing surface of the pulmonary mucosa is involved to such extent as to interfere with proper metabolic oxygenation. (2) Elimination, (*a*) by the liver and bowel through the vigorous use of calomel and salts; (*b*) by the skin through sweats induced by external heat; (*c*) through withdrawal of blood when indicated by right heart-distention. (3) Stimulation of heart by strychnine, alcohol or ammonium carbonate and in suitable cases by the subcutaneous injection of normal salt solution. (4) The local treatment of the lung by leeching, wet cupping, or dry cupping, as indicated.

The Dietetic Treatment of Arteriosclerosis.—Thomas B. Coley presents a most interesting paper on this subject. He declares that in the management of arteriosclerosis we must consider the long course of the affection and the fact that the damage which has been done cannot be repaired. The physician should aim to arrest the process and make the development of serious complications less likely. Whatever his age, the patient with arterial sclerosis is to be regarded as an old man whose work must be of the lightest character and whose life must be made as easy as possible. The writer gives the following suggestions concerning dietetic restrictions: (1) The quantity of food should be greatly reduced, not more than one-half or two-thirds the general average for body weight being required. This amount in detail should be estimated according to the general rules laid down. (2) The quality of the food is important. Proteid foods are to be reduced, but not excluded. Meat should not be taken more than once daily, and then in small quantity. It should be our effort to see that the patient obtains well-cooked food, especially avoiding large amounts of fat or other substances difficult of digestion. Alcohol, tea, coffee, and cocoa, as well as tobacco, are to be forbidden or used with extreme moderation. Excessive water drinking, or drinking large quantities of any fluid must be curtailed. (3) The regulation of meals is important. Breakfast should consist of fruit, a cereal with cream and perhaps an egg, poached or soft-boiled. There should be an interval of five or six hours between breakfast and dinner, and the heaviest meal should be taken in the middle of the day. It is not advisable to place too many restrictions upon what the patient shall have for his dinner. It may consist of soup, fish, meat, and vegetables, but overfeeding is to be strenuously avoided. Between dinner and supper five or six hours should also elapse, and this meal must be light and consist, as breakfast, mainly of fruit and cereals. In general, a comparatively dry diet is indicated, and the patient should eat nothing between meals. Elimination must be kept at its maximum of efficiency, and hygienic regulation laid down in great detail and strictly enforced.

New York Medical Journal, February 13, 1904.

Personal Experiences with the Administration of Nitrous Oxide and Oxygen for Prolonged Anæsthesia.—P. Le Breton tabulates eighteen cases in which the above-named combination of gases was employed for anæsthesia. The longest time of operation was one hour and a quarter. The author believes that the combination is for prolonged anæsthesia satisfactory but limited in application. The wealthy class alone can demand it, because of the cost of materials and the larger fee for the engagement of an experienced anæsthetist. The bulky and expensive apparatus, and the difficult method of administration are not inviting, and the occasional lack of smoothness in the narcosis discomforts the surgeon. Hence the employment of this method will be reserved for anæsthetists in the larger cities, in the case of operations upon the extremities or trunk where the condition of the patient demands an anæsthesia free from danger and practically free from after-effects. The deserving increasing popularity of the gas and ether combination predicts a similar popularity of the use of

gas, oxygen and ether, when the gases are used until the incision is made and after the suturing is begun, and the ether provides complete relaxation and freedom from cyanosis during the operation proper. The contraindications are chronic alcoholism and well-marked arteriosclerosis or cardiac lesions.

Original Research Regarding Human Perspiration.—J. H. Hoelscher describes his method of procuring normal sweat without loss by evaporation and as free as possible from skin impurities, and then describes the peculiarities of the sweat following the exhibition of various remedies. From his experiments, he draws the following general conclusions: First, the hot-air bath causes an aseptic fever despite the antipyretic action of acetanilid, sodium salicylate and quinine, given with the bath; second, the hot-air bath given in uræmic states shows a sweat with increased urea and nitrogen; third, in articular rheumatism, in conjunction with the salicylates, the hot-air bath gives more rapid results and lessens cinchonism; fourth, certain types of myocarditis are benefited by the hot-air bath; fifth, pilocarpine should never be used without the aid of hot applications to the body. So combined, there is no sialagogue and less toxic drug effect, and far more sweating than otherwise; sixth, three cases of catarrhal jaundice were sweated; all the modern tests failed to disclose the presence of bile pigments in the sweat; only the epithelial débris containing bile deposits; seventh, modern sugar tests failed to reveal the presence of sugar in sweat obtained from diabetics; eighth, a case of chronic constipation and indicanuria did not diclose the presence of indol or skatol in the sweat; ninth, regarding the function of eliminating normal and abnormal substances, the skin is not to be compared with the kidneys; tenth, free sweating seems to affect favorably the course of psoriasis. This statement, however, needs to be sustained by more research. Finally so, the effect on other skin diseases. Lastly, 1500 c.c. of sweat contain about eleven and one-half grams of solids (nearly three drachms), one-half organic and one-half organic; about six decigrams (one grains) of urea; and about .47 centigram (eight grains) of nitrogen.

American Medicine, February 13, 1904.

Facial Paralysis.—Norton L. Wilson enumerates various etiological factors possible in relation to facial paralysis. The diagnosis or location of the lesion is important, as the prognosis depends upon its location. As to treatment, electricity should not be applied until the end of the third week, except to ascertain the excitability of the muscles. Then electricity and massage should be used regularly and systematically. If the muscles respond to faradism, that current should be used. If they do not respond to the induced current, galvanism should be used, but only with the galvanometer. Flannel wrung out of hot water or the hot-water bag does something by relieving the stiffness and dilating the vessels for the first few days. The ear and eye should receive the proper attention. Internal medication is of little or no value.

Myxoneurosis Intestinalis Membranacea.—C. A. Ewald states that there are a great many reasons why myxoneurosis is of a nervous nature. The cases are most frequent in women, and are often accompanied by some genital disturbance, coming especially during the climacteric and disappearing when this period is passed. Diet plays a very important part in the treatment. Specially efficacious when simple constipation accompanies the myxoneurosis are the coarse breads; fats, as butter, cream, salads with oil; fatty sauces, gravies; coarse vegetables of the cabbage family; curded milk with plenty of sugar; fruit juices, figs, syrup, jams, prunes, stewed fruits, and fresh vegetables of all kinds. In the cases not complicated by constipation the results of diabetic treatment are not marked. Through better nourishment, however, the hysteria and neurasthenia are directly benefited.

The Prevention and Treatment of Puerperal Infection.—Richard C. Norris declares that autoinfection is a term rarely to be employed, and usually should be reserved for the one who wishes a cloak for his ignorance. The prevention of puerperal infection guided by the most recent results of bacteriology requires a study of three important details of technique: (1) The antepartum toilet of the patient; (2) hand sterilization and the dangers of vaginal examination; (3) the immediate repair of injuries to the birth canal. The writer says that antiseptic vaginal douches are unnecessary, and may be detrimental in normal cases. The use of sterilized rubber gloves is most valuable. The antiseptic solutions should always be made with boiled water. All instruments should be boiled before they are used. Careful inspection should be made of the vaginal mucous membrane from cervix to vulva. It must be remembered that the upper part of the parturient canal is more susceptible to infection. After an early diagnosis of infection has been made, the infected area, usually within the uterus, should be inspected by the finger to determine if possible whether we have to deal with putrid absorption from decomposing débris or the smooth endometrium of septic infection. The appropriate cases for curettage are those in which the uterus contains débris. The writer believes the best results to follow the use of a sharp curette. When the endometrium is smooth, there is no need for scraping. Following curettage, the question of the douche is under discussion at the present time. For putrid endometritus a disinfecting douche is indicated, according to the writer. Strong antiseptics are not only useless but dangerous. Salpingitis that progresses to abscess formation requires evacuation and drainage. Injured or infected ovarian or uterine tumors should be removed after labor. Hysterectomy for puerperal infection is by no means a settled question. Ligation or excision of the uterine or spermatic veins when they are the seat of thrombosis with pyæmic symptoms is the latest attempt to reach by surgery a very dangerous type of puerperal infection. The gravest forms of puerperal infection can very often be prevented by the early recognition of beginning infection and the prompt resort to the well-tried methods of treatment.

British Medical Journal, January 30, 1904.

Infection in Acute Rheumatism.—W. P. Le Feuvre recalls several cases which suggest infection in acute rheumatism. One patient was a railway guard. He used the same room and bed alternately with a fellow-guard. He had scarcely recovered from an attack of acute rheumatism before his room-mate was for the first time in his life similarly attacked. In the latter case there was no trace in personal or family history of any rheumatic taint. There was nothing in the position or neighborhood of the guards' quarters to suggest a cause for the attack. Another case is mentioned of a mother who came to nurse her daughter during an attack, and suffered similarly after about a week's interval. The writer says he has noted two or three similar cases.

Vasectomy for Enlarged Prostate.—Thos. Alph. Buck reports the history of an interesting case. The patient was of fat and flabby physique, aged fifty-eight and married. He was very regular in all his habits. He exhibited symptoms of enlarged prostate. Micturition was frequent both day and night. At times there was almost absolute retention, urine being voided only by drops and with extreme pain and violent strain. The prostate was uniformly enlarged like a medium-sized apple. The condition of the patient was one of chronic invalidism. No catheter could ever be passed, even under chloroform, though there was no stricture of the urethra, or spasm or pain on attempting to do so. The patient insisted upon operation. About one inch was excised from the right vas deferens. The patient experienced no discomfort and was up and about in six days. From this time he has had no difficulty in micturition or occasion to seek medical aid.

Notes on Myiasis.—P. S. Lelean in speaking of flies says that, of more recent years, perhaps the most curious biological contribution is that of Dr. Folker of Guatemala on the gusano worm. He describes the ovulation of this mosquito-like fly. After piercing its proboscis into the skin, it passes the "tail" along it as along a director, and deposits a full charge of ova into the cavity. A boil ensues in three days. From a pathological standpoint, Bruce's recent demonstration of the *rôle* of Glossinapalpalis in sleeping sickness stands alone in importance. As to treatment, the natives occlude the orifice of the cavity in which the larva is contained by a piece of stamp paper; the air-breathing parasite, being thus asphyxiated, can be expressed. The aperture is covered with a tobacco-leaf, the nicotine poisoning the grub. Folker uses a hypodermic of chloroform, which so paralyzes the larvæ that he has by this means expressed as many as fourteen in less than two minutes, a velocity which commands respect. The Dermatobia noxialis (screw worm) is killed in the frontal sinus by carbolic injections of a two-per-cent. solution. In the auditory meatus the larvæ often cause so much tenderness as to make mechanical extraction impossible. A little calomel blown into the meatus is said to cause their death and spontaneous extension. In India it has been found that maggots ingested in mangoes are most difficult to dislodge, a fact not to be wondered at when they survived five minutes' immersion in pure carbolic acid. One patient passed from 50 to 110 larvæ daily for twelve months, and greatly feared their eating through the intestine. One case was cured by enemata terebinthinæ; another was on buteafrondosa, and in a third—parasiticides having no effect—scybala were produced by opium, and the embedded maggots came away by subsequent use of purgatives and enemata. Finally, in huts infected by diptera, if cones of dried pyrethrum powder

be burnt, the flies fall stupefied to the floor, whence they can be collected and burnt.

Berliner klinische Wochenschrift, January 25, 1904.

Syphilis and Tabes.—Erb reviews the pros and cons of the syphilogenic theory of tabes, and reasserts his former views on the subject. The only conclusion that can be drawn from the accumulated statistics is, he thinks, that tabes stands in close relationship to syphilis, and, in most cases, originates solely in consequence of a preliminary syphilitic infection. The question, however, of whether this is its exclusive etiology, and whether every single case of the disease has its origin in a former syphilis, cannot yet be answered in the affirmative, though this is probably the case.

The Active Immunization of Man against the Typhoid Bacillus.—Shiga made observations on the agglutinating and bactericidal powers of his own blood serum and that of a colleague after immunization with free receptors. This was done by injecting the product obtained by mixing a one-day agar culture with 5 c.c. of sterile physiological salt solution, heating for one hour at 60°, keeping at 37° for two days, and filtering through a Reichel bougie. The filtrate was tested to determine the absence of germs. Small amounts (0.05 to 0.5 c.c.) were injected and produced practically no local or general effects. Eight days afer the last injection, agglutination was produced by the author's serum in a dilution of 1 to 640 and in that of the other subject in a dilution of 1 to 80. The difference is referred to the fact that the author had suffered an attack of typhoid fever twelve years previously; preliminary control tests had, however, been negative. The bactericidal value of the sera was also tested and found to be well marked.

The Etiology and Pathology of Tabes, Especially Its Relation to Syphilis.—Lesser seeks to reconcile the various objections that have been brought against the theory of the syphilitic origin of tabes, and the views of the adherents of this doctrine, by considering tabes as belonging to a third class of syphilitic lesions. The group ordinarily considered as secondary lesions comprises the papular manifestations which are found almost exclusively in the skin and mucous membranes, occur in the first few years of the disease, are susceptible to treatment by mercury, and are infiltrations. The tertiary or gummatous lesions are found in all regions, are chronic, and found mostly in the later years of the disease, and are susceptible to treatment with iodides. Under the heading of *quaternary* lesions, the author would establish a class in which interstitial inflammations of a proliferative nature occur and attack the inner organs many years after the initial infection. These are resistant both to mercury and the iodides, and comprise such lesions as tabes, syphilitic contracture of the liver, smooth atrophy of the tongue, etc. By adopting this class of quaternary lesions, the author is able to take up in detail and refute all the objections of the opponents of the syphilogenic theory, and the conclusion he reaches is that most cases are due to the specific infection. Aneurysm occupies much the same relation to syphilis as tabes, and is also comprised in this class of quaternary lesions.

Münchener medizinische Wochenschrift, January 19, 1904.

Eosinophile Cells in Sputum.—Hildebrandt summarizes the conclusions of various writers on the occurrence and significance of eosinophile cells in the sputum. These are very contradictory, but agree in assigning more or less importance to the presence of these cells. The author made observations on a variety of cases, including asthma, acute and chronic pulmonary tuberculosis, acute bronchitis, lobar pneumonia, etc., and found that the cells were present in each in sufficient numbers to render futile all attempts at establishing diagnostic rules. In particular, the presence of eosinophile cells in the sputum is not characteristic of bronchial asthma, nor is it evidence against the existence of pulmonary tuberculosis, as some authorities claim.

Observations on the Diazo-reaction, Koplik's Spots, and the Temperature in Measles.—Müller observed these features in an epidemic of measles in Marburg, in which two hundred and fifteen cases were treated in the polyclinic. The diazo-reaction was found present in nearly all cases at the acme of the disease, but usually it appears only with the eruption, and is therefore not an early symptom. Koplik's spots are a valuable early symptom since they frequently appear on the first day and are found in at least 80 per cent. of the cases. They are not pathognomonic of measles, however, since they were repeatedly observed in rötein also. In most uncomplicated cases the temperature follows the classical course, exhibiting a short, sharp rise in the catarrhal stage followed by an intermission of one to two days and then remaining high for about four days, finally falling by crisis. Types described by Jürgensen were also seen, viz., a gradual remittent rise or a sudden sharp rise remaining continuously high.

Serious Consequences of Deep Cervical Incisions in Labor.—Hofmeier describes two cases in which this method of facilitating delivery, first advocated by Dührssen, had very serious results. In the first case the incisions were made by another obstetrician three years previously. When the patient came under the author's treatment it was found that the cervical canal from its middle upward was the seat of a firm cicatricial stenosis. As no advance in dilatation was made after the patient had been having severe pains all night a careful instrumental dilatation of the cervix was done and the child perforated and extracted. In the other case the author himself, in 1897, incised the cervix, owing to its unyielding nature. The incision was very slight, but furious bleeding was set up which could be checked only after a rapid instrumental delivery had made the parts accessible. Two subsequent deliveries were uneventful, but the fourth was protracted, and owing to the rigid scar tissue the cervix and lower uterine zone were ruptured by the advancing head, and the resulting hemorrhage cost the patient her life. If incisions must be made the author recommends that they shall be antero-posterior and not placed laterally.

Suture of the Heart.—Georges Renon thinks that all wounds of the pectoral region with considerable hemorrhage, either external or internal, should make one think of an injury to the heart and require immediate surgical intervention. This should be carried out aseptically and as rapidly as possible, suturing the wound round the finger. Drainage is not called for. Venous injections or large subcutaneous injections are to be avoided. The case reported was in a man of twenty-three years with a stab wound in the chest made by a large pocket-knife. Before the operation of closing the wound he was considerably exsanguinated by the profuse hemorrhage. The wound was exposed by a transverse cut and many clots were found and removed. A violent hemorrhage followed, which was only partially controlled by inserting the finger into the wound in the heart. The muscle was quickly sutured and drawn together, completely stopping the leakage, and the pericardium was emptied and sewn up, leaving a small drain. By this time the patient was nearly collapsed, and transfusion was done. The condition of the wound continued good all except a great flow of serum from the pericardium. The patient died the next night. At the autopsy it was seen that the suture had held perfectly and there had been no leakage into the pericardium. The wound, which at the time of operation was thought to be at the base, was found at the apex of the left ventricle.—*La Tribune Médicale*, January 16, 1904.

The Treatment of Uncomplicated Goiter with Intraglandular Injection of Iodized Oil.—Dubar thinks local treatment as practised by rhinologists and ophthalmologists for combating infection is suggestive of possible good results if applied to other parts of the body. The cases of goiter he cites sustain his expectations. He thinks that if there is a local need of a certain substance it may be useless or even dangerous to place it in some other part. The oil used contained 40 per cent. iodine and the dose averaged 5 c.c. per day for ten days. In one of the author's cases after injecting one c.c. in weekly injections for nine times, the goiter had shrunk from 34 to 32 cm. In the second case after six similar injections the goiter shrank from 38 to 35.5 cm. Four injections more reduced it to 34.5 cm. He noted an absence of reaction after the injection, which made him think that in the oil the iodine formed a true chemical compound. The author admits that he had noticed nodes after the injections of iodized oil, but says that these nodes were always reabsorbed.—*Le Progrès Médical*, January 23, 1904.

Grocco's Paravertebral Triangle.—C. Baduel and L. Siciliano state that under normal conditions percussion of the vertebral column shows good resonance as far down as the base of the lungs. This resonance is impaired by the presence of fluid in either pleural cavity. The triangle of Grocco is the triangular area of dulness in the neighborhood of an effusion. This triangle is a very important symptom in the differential diagnosis between pleuritic effusion and pulmonic consolidation and to a lesser degree between pleuritis with effusion and without. The triangular dulness begins at about the same height as the upper edge of the fluid, while in the other two affections there is a margin of the affected area which does not give this sign. But the peculiar feature is that in the pleuritic effusion the triangular dulness is found on the opposite side of the vertebræ to that of the fluid.—*Rivista Critica di Clinica Medica*, January 16, 1904.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 4, 1904.

ANDREW H. SMITH, M.D., PRESIDENT.

Action on Proposed Amendments to Constitution and By-Laws.—It was moved and carried that the number of Fellows elected as such shall not exceed one thousand, and at least three-fourths of this number shall be residents of the City of New York. It was also moved and carried that the library should be open to the public from 9.30 A.M. to 1 P.M. and to members of the Academy from 9.30 A.M. to 10.30 P.M. Books can now be taken out by members only when for their personal use.

Lesions Peculiar to the Pancreas and Their Clinical Aspect.—Dr. EUGENE L. OPIE of Baltimore read this paper. He said that to the clinician the characteristic feature of pancreatic disease was doubtless the obscurity of its symptoms. Sometimes extensive destructive changes were unaccompanied by recognizable symptoms. Recognition of pancreatic disease was further complicated by the fact that lesions of that gland were seldom primary but were dependent upon changes in other organs, notably in the duodenum, liver, or bile passages. He said that an understanding of the peculiar pathology of the pancreas and of its relation to that of other organs was therefore essential to the diagnosis of pancreatic disease. He divided diseases of the pancreas into the following two groups: first, those that effect the secreting apparatus of the gland and, second, those which had their seat in the islands of Langerhans and interfered with the influence which those structures exerted on carbohydrate metabolism. He then mentioned some recently demonstrated facts which concerned the physiology of the pancreatic juice, the so-called external secretion of the organ, although their bearing upon clinical medicine and upon pathology might not as yet be evident, they serve to show the complexity of the pancreatic functions. The activity of the pancreatic juice was in considerable part dependent upon the secretions with which it came into contact after it had entered the intestine. He next considered the effects of pancreatic juice when it was diverted from its proper channels into the tissues about the organ, causing the characteristic lesion, but since it was usually confined to the adipose tissue of the abdominal cavity its diagnostic importance was only made manifest when the surgeon opened the abdomen. He referred to fat necrosis, which occurred only in association with disease of the pancreas. Circumscribed opaque white foci of necrosis were conspicuous upon the translucent yellow fat of the omentum, of the mesentery, and below the parietal peritoneum, and were recognized as soon as the peritoneal cavity was opened. He said acute hemorrhagic pancreatitis was most frequently associated with fat necrosis, and suppurative pancreatitis was less commonly found accompanying it. Fat necrosis might also accompany chronic interstitial pancreatitis or obstruction of the pancreatic duct caused by biliary or pancreatic calculi or by carcinoma compressing the duct. In order to explain the relation of fat necrosis to these various lesions it made it necessary for him to describe briefly its pathogenesis. The relationship between cholelithiasis and acute hemorrhagic pancreatitis was entered into. A review of forty-one reported cases in which gallstones had been found in association with acute pancreatitis had shown that a calculus in seven instances was lodged at the duodenal orifice of the common duct, and mechanical conditions favored the penetration of bile into the pancreas. The clinical aspect of certain facts described was the following: (1) The presence of jaundice or the history of previous attack of gallstone colic might give confirmation to the diagnosis of acute hemorrhagic pancreatitis when somewhat indefinite symptoms suggest the presence of this condition. (2) When at operation undertaken for the relief of obscure abdominal symptoms, disseminated fat necrosis indicated the presence of acute hemorrhagic pancreatitis, examination of the gall-bladder and bile passages would in a considerable proportion of cases reveal the presence of gallstones. Another lesion which had its origin in the secreting apparatus of the pancreas was the chronic inflammation which followed obstruction or ascending infection of the pancreatic ducts. He considered another group of lesions that inhibited primarily that influence which the organ exerted on metabolism through the medium of the circulation, *i.e.* the so-called internal function. Clinical observation had as early as 1788 shown that diabetes mellitus was frequently associated with grave disease of the pancreas, but the relationship of the pancreas to carbohydrate metabolism had not been clearly recognized until von Mering and Minkowski succeeded in completely extirpating the organ in dogs, and showed that in a few hours sugar appeared in the urine. The pancreas was essential to normal carbohydrate metabolism. It was evident that diabetes mellitus, or at least glycosuria, might be regarded as a symptom of pancreatic disease. The most commonly associated condition was undoubtedly chronic inflammation, causing an increase of the interstitial tissue of the gland. It must be born in mind that diabetes mellitus might occur without demonstrable changes in the pancreas; in at least one-third of the cases the organ was found by gross and microscopical examination to be normal. From facts cited, he made the following conclusion, that when diabetes mellitus was found in an individual suffering from cirrhosis of the liver, the former disease was dependent upon the co-existence of chronic interacinar pancreatitis, doubtless produced by the same etiological factor, in some cases alcoholic excess, which was responsible for the hepatic disease. There was another group of cases in which diabetes mellitus was found to be associated with advanced arterial sclerosis. Since the pancreas furnished to the blood a so-called internal secretion, perhaps a ferment, necessary to normal carbohydrate metabolism, and since diabetes mellitus resulted when the pancreas was no longer capable of supplying this need, he said the possibility of artificially replacing the defect had suggested itself. A number of observers soon found that the administration of pancreas or extracts derived from it and administered to dogs deprived of their pancreas failed to prevent glycosuria or diminish its severity when established. There was, however, clinical and experimental evidence to show that when diabetes was the result of a destructive lesion which inhibited the digestive function of the pancreas, some benefit might be obtained by supplying the intestine pancreatic ferments.

The Relation of Surgery to the Recent Advances in the Knowledge of the Pancreas.—Dr. GEORGE WOOLSEY read this paper. He said that on account of its physiological importance this organ could not be removed with impunity, for von Mering and Minkowski had shown that complete extirpation of the pancreas in dogs was followed invariably by symptoms of a fatal diabetes. These experimenters had also found that if a small portion of the gland remained, whether connected with the duct or not, there would be no glycosuria until that portion atrophied. Hence, with few exceptions, tumors of the pancreas could be removed without immediate danger of diabetes. Lack of pancreatic secretion in the intestines could be supplied by administering pancreatin, but the internal secretion could not be supplemented. He said that even incision into the pancreas had its dangers, not only from hemorrhage, but also from the fact that leakage may cause (1) A lack of peritoneal adhesions, leading to peritonitis, (2) a fat necrosis of the subperitoneal fat, and (3) a chronic fistula with irritation of the surrounding skin. The diagnosis, and treatment as well, of pancreatic disease was very much hindered because of the pancreas being so deeply situated in the upper part of the abdomen. Several points in the anatomy of the pancreas had been studied and emphasized in recent years,

and these Dr. Woolsey referred to. The relationship of the pancreatic duct to the diverticulum of Vater was noted; a stone impacted in this diverticulum might completely fill it and occlude both the biliary and pancreatic ducts. The association of pancreatitis with cholelithiasis was noted; as a prophylactic measure more general operative treatment for cholelithiasis was advocated. The severity and often rapidly fatal nature of the lesion was an important impediment to successful operative treatment. He favored the course to operate early in acute pancreatitis and not wait for recovery from the initial collapse, but to treat the latter by infusion, etc. On account of the rarity of acute or subacute pancreatitis few if any surgeons had had a large personal experience.

Diagnosis of Acute Pancreatitis.—He said it was the difficulty of diagnosis which more than anything else prevented a more rapid development of the surgery of pancreatitis. As a matter of fact, a diagnosis was seldom made until the operation or autopsy revealed it. In diagnosing acute and subacute pancreatitis, the subjective and objective symptoms and the disturbances of function were the means at the surgeon's disposal, and of the first two little or nothing could be said. The disturbed pancreatic function was almost invariably connected with chronic lesions productive of extensive destruction of the pancreatic tissue, or with interference with the passage of its secretion into the intestine. When this occurred, with or without diabetes, the patient was, as a rule, beyond the help of operative measures. But little or any light had been thrown on our knowledge of acute pancreatitis by recent advances. He believed that the severe acute form presented quite a charcteristic picture for the purpose of diagnosis and made a probable diagnosis lie within the realm of possibility. Its onset was sudden with intense, colicky epigastric pain, becoming general later, severe vomiting and eructations, and distension, rigidity and tenderness, especially of the upper abdomen. There was marked collapse and the face and extremities were cold, often cyanotic and covered with a cold sweat. The pulse was small and rapid and the temperature was not high, often subnormal. Motor disturbance of the stomach and bowels, *i.e.* vomiting and obstipation, were so commonly associated that a diagnosis of intestinal obstruction was most often made. If this symptom-complex occurred in connection with corpulence, alcoholism, gallstones, gastroduodenal catarrh, traumatism or arteriosclerosis, the diagnosis was made still more probable. Acute pancreatitis was often mistaken for and often could not be differentiated from acute perforative peritonitis or acute obstruction of the bowels, high up. The best means of diagnosis and treatment was an early laparotomy. The diagnosis he said would be established if the exploratory incision revealed a fat necrosis.

Treatment of Acute Pancreatitis.—He said that heretofore the expectant plan had been commonly advised until the symptoms of collapse had passed away, but the best judgment was now in favor of early operation. The severe cases die wthin the first four or five days, those that survive longer develop general peritonitis, local abscess or necrosis of the pancreas. In a few cases the progress was arrested. The question of early operative treatment was associated with that of the significance of the exudate. The pancreatic secretion from an injured pancreas mixed with blood had a very toxic effect and, in the peritoneal cavity, might so effect the peritoneum as to cause death. In acute pancreatitis he said we had a bacterial infection as well; even this may be, and often was, the cause of the pancreatitis. He said that some cases of so-called pancreatic apoplexy might run an aseptic course or the patient might die before the bacterial infection had had time to effect the peritoneal exudate. The peritoneal exudate in acute pancreatitis commonly contained bacteria, and the toxic and infectious nature of this exudate made its evacuation most necessary. This was borne out by the results obtained in early operation where merely evacuation, irrigation, and drainage were employed. Personally he believed this was all that could be done in these severe cases, and it could be done under cocaine.

Chronic Pancreatitis.—The occurrence of the chronic form was more common than the acute, and its etiology was usually a chronic catarrh of the pancreatic duct extending from a similar condition in the duodenum or common bile duct. If in addition to the pain and tender spot an inch above the umbilicus prolonged jaundice appeared, with or without a distended gall-bladder, probably a diagnosis could be made. Under anæsthesia an enlargement of the head of the pancreas could be made out. A diagnosis from cancer of the head of the pancreas was not easy even after exploratory incision. He said that Opie, Robson, and others had called attention to the close relationship existing between chronic pancreatitis and cholelithiasis. In the former jaundice was more unvarying, the gall-bladder more apt to be dilated, and there might be disturbances of function evidenced in the urine and stools. Exploratory operation was the proper course for diagnosis. Robson had shown that the condition could not only be relieved but completely cured by indirect drainage through the gall-bladder, by a cholecystostomy or cholecystenterostomy, thereby relieving the tension, congestion, and inflammation of the head of the pancreas.

Cysts of the Pancreas.—The most common lesion, so far as the number of operations were concerned, had for a common cause chronic pancreatitis; the occurrence of this retention cyst added another reason for early diagnosis and operation for chronic pancreatitis and its common cause or associate, cholelithiasis. He said that pseudo- or peri-pancreatic cysts had been shown to constitute a large proportion of so-called pancreatic cysts. The commonest and safest operation he believed to be incision and drainage after fastening the cyst to the anterior abdominal wall, *i.e.* so-called marsupialization. Tumors of the pancreas gave a less favorable outlook. Unfortunately these cases are left too long and not referred to the surgeon early enough.

Conclusions.—He urged the more general use of Hahn's method of operating for acute pancreatitis in the early stages, by evacuation, irrigation, and drainage; he emphasized the fact that as several serious lesions of the pancreas may be due directly or indirectly to cholelithiasis, we were provided with another indication for more frequently operating upon the latter; he suggested that as an exploratory operation was the only way of making a diagnosis in many cases of pancreatic disorder, and as these as well as the conditions they resembled also demanded operative treatment, they should not hesitate to advise early resort to it in case of any doubt. The diagnosis of an indication for exploratory incision was all that was absolutely necessary.

Dr. R. F. Weir said that surgeons were indebted in pancreatic diseases as well as in appendicitis to the wisdom and astuteness of a physician, Dr. Fitz of Boston, who was the first to call attention to certain points of importance in pathological changes in both organs. In his past experience he recalled two cases of pancreatitis which were discovered only after opening the abdomen for some obscure surgical condition. In each instance he had found fat necrosis. Not being able then to interpret the case, he went on with the treatment of cleansing and draining, with indifferent results. He said that, after all, these troubles presented themselves to the surgeon in two ways, the acute and chronic stage, the former being extremely difficult of diagnosis. There is a series of symptoms which point to trouble in the upper part of the abdomen, and, in efforts at diagnosis, one should carry in mind the pathological conditions

which might occur there and attempt to arrive at a diagnosis by exclusion. In the acute form of pancreatitis, whether hemorrhagic or suppurative, he called attention to the statement made by Murphy of Chicago, that an examination of the blood would assist us; the white cells were not increased in hemorrhagic pancreatitis. He referred to the relation of a case by Dr. Eliot a short time ago, in which, on opening the abdomen, much fat was noticed in the mesentery and a bloody serum in the abdominal cavity; this latter point he believed to be an important sign because of the few conditions which might give rise to it outside of trauma, intense strangulation, or thrombosus. This was also to be found in hemorrhagic pancreatitis. In Eliot's case the fluid was found in the right flank high up and came through the foramen of Winslow. The treatment of acute pancreatitis was very unsatisfactory. He referred to the remarks of Mikulicz before the American Association of Surgeons held in Washington last year; he stated that out of forty-six cases operated upon only nine recovered. In four of these recovery was due to the sponging out of the bloody secretion; this secretion was an irritating and poisonous one. Drainage was accomplished either anteriorly or posteriorly with but little disturbance. During the past two years he had seen three cases which pointed to the passage of gallstones, but none were found; there was, however, an enlargement of the head of the pancreas. In four cases the condition was associated with the presence of gallstones; after extraction of these and the institution of drainage, the patients were relieved.

Dr. MORRIS MANGES again referred to the first case of acute pancreatitis operated upon in this city. One and a half years after the operation and discharge from the hospital, the patient developed diabetes. At the time of operation no sugar could be determined. This patient complained chiefly of constant pain, worse after eating. He said that Dr. Lilienthal had a case of supposed intestinal obstruction which proved to be one of pancreatitis. This patient gave a picture of intense pain, excessive vomiting, and collapse. He recalled a case of pancreatic fistula in which operation was declined, and the patient grew very much emaciated from loss of the pancreatic juice. Dr. Lilienthal was asked to see the case and advised the administration of pancreatin in large doses, and much surprise was expressed at the rapid recovery which followed.

Dr. E. LIBMAN spoke of an interesting observation made in which there was a perforation in the upper part of the duodenum, and about that perforation was found a fatty necrosis, particularly in the omentum. The secretions there, leaking out, had caused the necrosis. He did not consider the presence of bloody fluid of much diagnostic import unless it was of chocolate color.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 14, 1904.

DAVID BOVAIRD, JR., M.D., CHAIRMAN.

A Case of Diabetes Insipidus in a Child.—Dr. E. H. M. SILL reported this case. The patient was a boy of nine and a half years, born in New York City of Austrian parents. The family history was negative. He was healthy up to eighteen months ago, when it was noticed that he was passing large quantities of pale urine, and that he was suffering from excessive thirst. This developed after a severe fright. He was nervous, irritable, and easily fatigued. He complained of pains in the lumbar region. Recently he had been passing from five to twelve quarts of urine in the twenty-four hours. There was very little sweating; the mouth was always dry. The urine was feebly acid, had a specific gravity of 1005, and contained neither albumin nor sugar. The quantity of urea varied between 18 and 30 grams in the twenty-four hours. He had been taking fifteen drops of the fluid extract of ergot, three times a day, and had had warm baths. The speaker said that this affection was very rare in children. A case had been reported by Dickinson, occurring in a new-born infant and it was by no means unknown in children of five years. Of thirty-five cases collected by one author twenty-one occurred under ten years of age, and nine under five years of age. The disease was noted chiefly after fright, sunstroke, lesions of the solar plexus and injury to some portion of the cerebrospinal axis. As a rule, the urine of these patients did not contain any abnormal ingredient. The disease was essentially chronic and of indefinite duration. Out of seventy-seven cases reported by Roberts, there were sixteen complete recoveries and fourteen fatalities, while in forty-seven there was an amelioration of the symptoms. Ergot, valerian, and electricity had been recommended in the treatment of this disease.

Dr. SARA WELT-KAKELS said she had seen two cases of this disease in children. One of them was a girl of nine and a half years, splendidly developed mentally, but of poor physique. The skin was dry and the appetite bad. The disease had existed for about three years before coming under her observation. The quantity of fluid taken had been restricted previously, but she was at once allowed to drink all the water she pleased, and this quickly improved the general condition. The child took between four and five quarts of fluid. The specific gravity of the urine varied between 1000 and 1003, and the quantity of urea was 0.1 per cent. The child remained under treatment about ten months, and gained about eight pounds during that time. Suddenly a paresis of the branches of the oculomotor nerve developed. The child was then lost sight of for a time, but it was learned that she became ill and died after a few days. She had tried various remedies, and obtained the best results from the administration of antipyrin.

The second case was that of a boy of six years, very well developed. He was passing from ten to twelve quarts of urine in the twenty-four hours, or about two-thirds of his weight. With the exception of the excessive thirst and the polyuria there were no symptoms. The quantity of urine was reduced to 8,640 c.c. under the influence of antipyrin. The reaction of the urine was faintly acid and the urine was almost colorless. No sugar was detected in the urine even by a number of tests. The quantity of urea excreted was about seven or eight grams above the normal. With regard to the differential diagnosis the speaker said that it was essential to exclude contracted kidney in making the diagnosis of diabetes insipidus.

Dr. JAMES J. WALSH reported a still younger case, that of a girl of sixteen months who fell out of bed. The mother told him that the child was urinating excessively, and although unable to speak, made noises indicating thirst. The child passed from four to six quarts of urine daily having a specific gravity of 1003. No treatment was given, and the child recovered. The disease had been present about three years ago.

Dr. C. HERRMAN said he had tried suprarenal extract in a case of diabetes insipidus, and it had had a marked effect on the quantity of urine secreted. Since then he had used this remedy in one or two cases with some success.

The Symptomatology, Differential Diagnosis, and Course of Bronchopneumonia in Children.—Dr. MATTHIAS NICOLL, Jr., read this paper. Bronchopneumonia was essentially a disease of the poor and unfortunate. This paper was based upon an analysis of 167 cases of so-called primary bronchopneumonia occurring during the past three years in the New York Foundling Hospital. It was exceptional at this institution to find at autopsy lungs free from pneumonic lesions.

Bronchopneumonia was essentially a secondary or complicating disease. Unlike lobar pneumonia, bronchopneumonia occurred at all seasons of the year; about two-thirds of the cases referred to occurred between December and May. Of one hundred and forty-seven cases in which the age was stated, 70 per cent. were in children under two years of age. The direct causes were exposure to cold, extension of the inflamma-

tion from the upper air passages downward, the acute infectious diseases, diarrhœa or anything which diminished the resisting powers of the child. There was no disease more uncertain in its course and outcome than bronchopneumonia. The onset was invariably sudden; the child became apathetic, refused to nurse or was irritable and restless. Vomiting was common; chills or convulsions were sometimes present. The skin was hot; the cry was curtailed and ended abruptly as though it caused pain. The temperature rose four or five degrees, and the respirations were usually forty or more per minute. The pulse-respiration was one to three or sometimes one to two. The alæ nasæ would be found to expand, and there might be more or less cyanosis. The cry would probably show unequal intensity on the two sides of the chest. Auscultation was by far the most important factor in arriving at a diagnosis in the early stages. Subcrepitant and fine râles should be diligently sought for, because taken in connection with the symptoms described they were conclusive proof of pulmonary congestion. Sometimes they were generally distributed; at other times, they were quite localized. Over areas of consolidation of considerable extent there might be bronchovesicular or bronchial breathing. Considerable areas of consolidation might be found at autopsy, of which during life there were no signs present except a few râles, and even these might be absent. It was not infrequent to note the physical signs of bronchopneumonia just before the occurrence of defervescence. In the mildest cases the average duration was about fourteen days. The disease might continue for one or two months with the development of changes in the lungs. In the cases which recovered the general tendency of the temperture was downward for the first two or three days. It was exceptional for the fever to terminate by crisis; it did so only nine times in the one hundred and sixty-seven cases. Cough might be entirely absent, but was often persistent or nagging. Suppression of the cough was seen in fatal cases. Vomiting was not frequently observed after the first few hours. The bowels were apt to be disturbed, the movements being green and slimy. Gaseous distention was often so severe as to embarass seriously the action of the diaphragm. Nervous symptoms were often very marked.

When a child under three years of age became suddenly and gravely ill, bronchopneumonia should always be thought of, and the same was true if, in the course of some other disease, there was a sudden rise of temperature and increase in the respirations. Fever alone in a young child was of but little diagnostic value. In measles, during the height of the fever the disturbance of the pulse-respiration ratio was the rule, and while this disturbance was noted in some other diseases of childhood, it was rare for it to persist for any length of time. The speaker did not think it was possible to distinguish clinically between disseminated bronchopneumonia and a capillary bronchitis. Fluid in the chest was commonly met with in children as a sequela of bronchopneumonia, and the fluid was apt to be pus. When bronchopneumonia occurred in the course of a laryngeal diphtheria, the diagnosis was sometimes difficult because of the transmission of the sounds by the trachea. Bronchopneumonia with exaggerated nervous phenomena might, at its onset, lead to an erroneous diagnosis of meningitis. Rigidity of the neck was not uncommon in pneumonia, and the apathetic expression bore some resemblance to the mask-like face of meningitis. In obscure acute febrile cases occurring in young children, the possibility of the existence of bronchopneumonia must never be overlooked.

The Treatment of Bronchopneumonia in Children.—Dr. WILLIAM P. NORTHRUP read this paper. He said that bronchopneumonia was a disease characterized by irregularities. The prognosis was uncertain because, in the secondary cases, the child was already exhausted by the previous disease. Given, a young tissue, mixed infection of pus-forming cocci, in a subject exhausted by previous disease, one had all the elements to account for all the irregularities of onset, course, ending, and pathological findings. At the autopsy, masses were found in one lobe, or masses in all of the lobes, or, perhaps, a whole lobe was involved. It was evident, therefore, that the pulmonary apparatus was the seat of what might be called a pulmonary erysipelas or cellulitis. He thought this view of the disease was advantageous in considering the treatment. With regard to prophylaxis, the speaker said that immunizing measles cases, when grouped in institutions, prevented diphtheria and the consequent pneumonia. In the treatment of bronchopneumonia it was most important to secure the free admission of fresh air. There was nothing remarkable about having a sick-room at a temperature anywhere from 65° F. to 40° F., or for the nurse to wear wraps and gloves. He saw no reason for fearing that the patient would "catch cold." No one "got cold" from fresh air entering the nostrils or striking the oval of the face. He had no fear of a fever patient "catching cold" in bed. The patient should be given an abundance of fresh, cool air, in small quantities at a time. It favored elimination, and was refreshing. The one thing in treatment easily forgotten was the need for tranquility and restfulness. Pneumonia patients were nervously susceptible to noise and confusion, and consequently a tearful grandmother must be removed and a congenial and tactful nurse placed in charge. It was also important to secure a free evacuation of the bowels. At the outset this should be effected by *full* doses of castor oil, with or without a preceding dose of calomel. Indigestion should be carefully avoided, and this was best secured by careful regulation of the diet. It was especially necessary to guard against intestinal distention, and when this was present it should be relieved by high irrigations of the colon with saline solution. Excessive fever should be reduced by measures which would not disturb or injure the child. The clinical thermometer was often an actual detriment in a case of pneumonia. Instead of relying upon this instrument it was far better to watch closely the patient's appearance and breathing and use good judgment. What the thermometer read made very little difference. The ice-cap was hardly to be recommended because of the non-conducting properties of the hair; it was better to apply a moistened cloth to the forehead. The nurse should be advised to feel of the feet and watch the respirations rather than take the temperature. If the feet were cold, and the pulse poor, give a hot foot bath under the bed clothes, as it would prove, under these conditions, an admirable cardiac stimulant. Constriction of the chest and the use of heavy poultices should be avoided. The garments should be changed often enough to avoid maceration of the skin. He avoided steam tents; they were good in spasmodic laryngitis, but not in pneumonia, as they robbed the patient of oxygen and macerated the little one. The speaker said he had never seen anything but good from giving plenty of water and fresh air to pneumonia patients, and any who had seen the manifest improvement following the opening of the windows, even in the coldest weather, must be impressed with the advantages of this treatment.

Dr. L. EMMETT HOLT opened the discussion. He said that he very heartily concurred in almost all that Dr. Northrup had said. He thought the greatest mistake in teaching and practice was in not giving enough attention to the hygienic treatment of disease. The average student of medicine was led to believe that the only method of getting well was by the administration of drugs. Perhaps in no other disease was the hygienic treatment so important as in pneumonia. He would place all of the cases of bronchopneumonia in the same class. In his opinion it would be a great mistake to have the impression go out that every case of bronchopneumonia was to be treated by the cold-air method advocated so vigorously by Dr. Northrup, although he was free to admit that a great many cases of this disease should be so treated. Personally

he believed that steam was useful in infants desperately ill with bronchopneumonia, and having only a moderate temperature.

Dr. FLOYD M. CRANDALL said he was very glad that the previous speakers had emphasized so well what not to do rather than what to do. If there was one thing to be taught the medical profession to-day it was that they were too strenuous in the treatment of pneumonia. It seemed to be the one disease which stirred the physician up to the point of wearing the patient out. The same thing might have been said a few years ago of diphtheria. He suspected that some of the results of the antitoxin treatment were due to the fact that we left our patients with diphtheria alone now, giving them an opportunity to get well, instead of wearing out their strength and preventing them from getting needful rest and sleep.

The Determining Factor in Lobar and Bronchopneumonia.—Dr. AUGUSTUS WADSWORTH referred to some animal experiments that he had made. At first, exudates of pneumonia cases of varying grades of virulence were injected subcutaneously, intravenously, or into the trachea or thorax. Of the various modes of inoculation, the most important proved to be tracheal injection. At first the inoculations were made in normal animals, and in most instances the virulent organisms caused a bacteriæmic type of infection without much lung lesion, or, if the organisms were not especially virulent, no lesions at all appeared in the lung. In a few instances bronchopneumonic types of lesion were found, but they were rarely diffused. The animals were subjected to trauma, to cold and to the injection of irritating substances, and it was found that the lesions of the lungs developed more freely and were usually bronchopneumonic; but if very virulent cultures were employed, the bacteriæmic type of infection, without lung lesion, was more apt to occur. Where lobar lesions developed, the animals appeared to be more resistant to infection. Continuing the investigation, it was found that bronchopneumonia was developed in susceptible animals when virulent cultures, or cultures of moderate virulence, were introduced, and that lobar pneumonia was extremely difficult to incite in an animal, this being possible only by obtaining a specially fine balancing of the virulence of the organism and of the susceptibility of the animal. The next step was to immunize the animals, injecting low-virulence and high-virulence micrococci. With the latter he obtained a lobar type of lesion when the animal was protected. If the resistance were not sufficient to prevent the organisms from producing the bacteriæmic type of infection, the lesions were more of the bronchopneumonic type. The bronchopneumonia of childhood, occurring after the infectious diseases, and the bronchopneumonias which develop in special races of men, were analogous to the bronchopneumonias developing in a more susceptible animal. The lobar pneumonia developing in a resistant and immunized animal was comparable with the lobar pneumonia which developed in the healthy and robust adult. The gravity of prognosis depended largely upon the likelihood of the development of a general infection rather than upon the extent of lesion, which was, after all, a conservative process.

Dr. S. A. KNOPF expressed his delight in learning that an acute pulmonary disease, such as pneumonia, was treated now by the hygienic and dietetic methods which had proved so useful for many years in a chronic disease of the lung—tuberculosis. He would say, however, that the cold-air treatment should not be given all at once, but rather gradually. He heartily approved of the plan of giving digitalis from the beginning of the pneumonia, thus anticipating the failure of the heart.

Dr. ANTHONY BASSLER said that in the past few years he had certainly seen cases which he would not like to classify as bronchopneumonia, and which were not ordinary bronchitis. For this reason he wished to retain the term, capillary bronchitis.

Dr. C. G. KERLEY said that there was no such thing as a simple or mild bronchitis in a very young child; in such a subject it should always be looked upon as dangerous. In the treatment of bronchopneumonia, our chief object should be to increase the powers of resistance as much as possible.

Dr. WALTER LESTER CARR emphasized this point, that some cases of infantile bronchitis showed a distinct respiratory spasm and demanded steam inhalations. In cases of bronchopneumonia in which there was a creeping process, counter-irritation should be made by the application of one part of mustard to six or eight of flour. Some of these cases did very well by the application of a hot water bottle to the feet. Others did well by raising the foot of the bed and so favoring the evacuation of the free secretion. The distention of the abdomen was no doubt at times due to toxæmia, but sometimes to an interference with the emptying of the veins and a disturbance of the usual action of the diaphragm.

Dr. NICOLL said that a number of cases analyzed by him, occurring in nursing children at the Foundling Hospital, gave a mortality of 40 per cent. The treatment in the institution was intelligent, but there was not nearly as much fresh air admitted as there should be. A case of disseminated bronchitis in the finer bronchi might just as well be considered clinically as a bronchopneumonia, for, to all intents and purposes, it was a bronchopneumonia, and could kill just as readily as one presenting a good deal of consolidation.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held January 18, 1904.

ALEXANDER LAMBERT, M.D., PRESIDENT.

Thrombosis of the Mesenteric Vessels.—Dr. FREDERICK HOLME WIGGIN presented a specimen removed from a woman, thirty-five years of age, upon whom he had operated a year ago for multiple fibromata of the uterus. At the time of that operation considerable difficulty was experienced because of the firm and extensive intestinal adhesions. These had been produced by a peritonitis that had followed an abortion some years previously. The left ovary was found to be cystic, so the cyst and a portion of the ovary were removed. The patient's condition was such that he had not stopped to examine the cæcum. Undoubtedly the appendix was disturbed by the separation of the adhesions, as shown by the fact that convalescence was interfered with by the occurrence of an attack of appendicitis. Within three months of this operation, an examination showed a cyst developing from the stump of the ovary, thus affording another argument against the so-called conservative surgery of the ovary. Some time afterward there was another attack of appendicitis, and she was urged to have an interval operation. She delayed, however, and did not come again under observation until January 4. She then stated that on December 31 she suffered from a slight attack of indigestion. On January 3 there were present symptoms of intestinal obstruction, and although her condition was very bad, operation was undertaken after two quarts of saline solution had been infused and she had been revived somewhat by the hypodermic administration of ergot and strychnine. On opening the abdomen, about one gallon of liquid fæces was found, and to the left of the median line, at the point of the greatest pain, the intestine was perfectly black, and there was a perforation, about half an inch in diameter. This portion of the bowel was excised, and an end-to-end anastomosis effected. The appendix was found to be adherent in the neighborhood of this mesentery, its tip being of a very bright scarlet color. The operation lasted about fifty-five minutes, and at the close the pulse appeared to be better than at the beginning, although still very feeble. About five hours after the operation she began to vomit, and during this effort the heart ceased to beat, and she could not be resuscitated. The pathologist, Dr. Oertel, reported that the intestine showed deep

hemorrhagic infiltration with œdematous swelling and increase of all the tissues. The vessels were much dilated and thromboses. Probably the thrombus formed there on January 2, although associated with but little serious constitutional disturbance. The speaker thought this case was an argument in favor of prompt surgical interference in cases of appendicitis. It was worthy of note, he said, that at the first operations the adhesions were broken up and the abdomen left full of salt solution, and that the second operation afforded an opportunity to demonstrate that adhesions did not necessarily re-form when broken and this line of treatment adopted.

Dr. HENRY GRISWOLD said that he had seen this patient last June, at which time there was considerable inflammatory reaction, and also much pain over the same side. On January 2 there were pain in the hypogastrium, vomiting, and diarrhœa. She was examined by him for appendicitis, but he could not find any evidence of this condition. The pain persisted on the left side. Her pulse was 62 and temperature 98.5° F. in the vagina. The next afternoon her condition was about the same, but twenty-four hours later she was in collapse, as had been already stated. Her condition seemed to him almost hopeless at the time she came under Dr. Wiggin's care.

Dr. JAMES T. GWATHMEY said that he gave the anæsthetic for this operation, beginning with the nitrous oxide and following this by oxygen and ether. Her pulse was 160 when she was placed on the table, and the radial pulse was imperceptible. After about twenty minutes the radial pulse could be felt, but only for a short time. At the end of the operation the pulsation in the carotid was rather stronger and fuller, and the beats about 140 to the minute.

Dr. ALEXANDER LAMBERT said he had seen two cases, one in hospital and the other in private practice. These presented a puzzling picture, and differed from all other forms of intestinal obstruction. The chief feature that impressed him was the peculiarity of the pain. One of the patients, a very intelligent physician, stated that each individual capillary appeared to be throbbing with pain. This man had appendicitis, and readily appreciated the different character of the pain. The speaker said that he had been unable to find on record a case of thrombosis or embolism of the mesentery that had been correctly diagnosticated before operation. Most of the patients suffering from this condition were those having cardiac or nephritic disease, but there was a certain number of young and apparently healthy persons in whom it had occurred, apparently primarily.

Dr. ROBERT T. MORRIS said that thrombosis of the vessels of the mesoappendix was fairly common. It was rather surprising that one did not more frequently meet with portal embolism.

The Treatment of Gunshot Wounds by the British Surgeons During the War of the Revolution.—Dr. STEPHEN SMITH read this paper (to be published later).

The Treatment of Gunshot Wounds During the Civil War.—Dr. ROBERT F. WEIR read this paper. He said that he was assistant surgeon in this war, and spent part of the time in charge of the base hospital of the campaigns in the Shenandoah valley. The capacity of this hospital in 1861 was 150 beds, but at the close of the war in 1865 its capacity was 3,000 beds. There were thirty thousand treated there, two-thirds of whom were wounded. It was interesting to note that only 0.37 per cent. were not gunshot wounds. The smallest projectile in general use at that time was the Colt's pistol bullet, weighing 207 grains. Rarely did wounds result from cannon balls, and no wounds from windage of cannon balls were recorded. Out of 245,000 gunshot wounds, there were but 359 from solid shot; 12,250 were from fragments of shells and 1,153 from grape and canister shot, while the balance was made up of wounds from various kinds of bullets. The conical ball did not always hold true to the direction of its axis. For the detection of bullets, the surgeons in this war made use of the porcelain-tipped probe of Nelaton, or, when this was not at hand, they used a piece of clay pipe or a clean sliver of Georgia pine. The best results in treatment were obtained by cleanliness, the use of plenty of water, and good ventilation. The wounds were smeared with simple cerate, a mixture of lard and wax, or else with some compound containing balsam of Peru. In the treatment of hospital gangrene, in the last years of the war, the best results were secured by the application of pure nitric acid. Dr. Weir said that the surviving surgeons must admit that death followed in the path of the surgeon. In those days the sponges were washed repeatedly in water, but were germ-laden, and were kept soaking in water, thus causing swarms of germs to develop. Pyæmia and secondary hemorrhage were among the most formidable complications encountered by the surgeons. In over 300 major amputations at this hospital, in only one case was total primary union obtained. What a contrast with our present results from aseptic treatment! The mortality from amputations of all kinds was 26 per cent., but of the major amputations it was about 42 per cent. The amputations in our civil hospitals shortly after the war, or before the advent of antiseptic surgery, was even greater than this. It was not until the last years of the war that any attempt was made to employ antiseptics. Then there was furnished to the hospitals a mixture of dry earth and cresylic acid, but it was not well received, and the results from its use did not counterbalance the dirt and annoyance attendant upon its employment. For fractures of the thigh, the extension treatment of Ruck, or the anterior extension splint of Nathan R. Smith was employed, and and for fractures of the upper extremity the recently introduced plaster-of-Paris bandage was employed. This method was first brought to New York by Gurdon Buck. Later, it was improved by Dr. James L. Little, and introduced into general military use. There existed among the lesser trials of the medical officer the difficulty of successfully carrying out the proper treatment of the medical or surgical malingerer; he was worse than a wounded man, for he was a bad example and a fraud upon the government. Chronic rheumatism was the favorite trouble feigned, but, perhaps, the affection most difficult to detect was feigned loss of voice.

Some Features in the Modern Treatment of Gunshot Wounds.—Major LOUIS A. LAGARDE, of the U. S. A., Washington, D. C., read a paper with this title. He said that the treatment of gunshot wounds to-day presented itself: (1) from experimental evidence; (2) from the *x*-ray evidence, and (3) from the local and general symptoms. The first proposition was that a gunshot wound was unclean and infected. Experiments on rabbits showed that the animals treated by simple dressings did the best of all, whereas those treated by such radical measures as swabbing with iodine or the application of the actual cautery, suppurated in every instance. In some recent tests it had been found that when the carbon particles were rubbed upon the skin of rabbits these particles were driven as far as 17 mm. into the track of the gunshot wounds, and that the distance these particles could be so driven inward depended upon the velocity and the sectional area of the bullet. It might be assumed that infectious matter on the skin or clothing would similarly penetrate the tissues. We should be content to treat gunshot wounds by cleansing the part and applying a clean dressing as soon as possible after the injury. Of course, the surgeon would refrain from using a probe of any kind, or even his clean finger, because the *x*-ray had supplanted all other methods of exploration.

Tetanus and the Toy Pistol.—Some gunshot wounds demanded treatment of a radical kind, but such could be given in civil or in military hospitals in time of peace only. Gunshot wounds produced at short range were of this class. The toy pistol was responsible for many such wounds in this country. In such cases the surgeon should at once resort to the use of tetanus antitoxin, after which he

should proceed to dress and clean the wound as he would an infected, contused, and lacerated wound from any other cause. These wounds were especially prone to suppuration. Of the virulent infections the tetanus was especially prone to develop. It was estimated that 400 cases of tetanus developed after toy-pistol injuries in this country last July. There was no question of the prophylactic value of the tetanus antitoxin in the laboratory, and recent cases were encouraging with regard to its action in private practice. Hæmatomata seemed to predispose especially to tetanus, and it had been demonstrated that burns increase this susceptibility to tetanus infection. Gunshot wounds were very apt to show hæmatomata in the track of the bullet. When the injury occurred from powder burns at close range, or from the toy pistol, the wound was one mass of contusion, and hæmatomata might be found, on microscopical examination, disposed around each powder grain. The influence of smokeless powder was probably the same, since seventeen cases of tetanus had been reported as having been produced by wounds from blank cartridges made with smokeless powder. It should be remembered that gunshot wounds favored the development of all infections, although tetanus was perhaps the most common infection. If infection with the bacillus aerogenes capsulatus occurred, the treatment must be very prompt. Welch had pointed out that this form of infection was most commonly met with in compound fractures, and next most frequently in gunshot wounds. When the entrance of a poisoned missile was suspected, a thorough examination of the weapon and of the ammunition should be made, culture and cover-slip preparations being made from the wounds of entrance and exit, and the ball, when removed, should be dropped into culture media. The treatment, if any, should be governed by the results of such bacteriological examination.

Influence of the Projectile on the Results.—The small steel-clad bullet was responsible for the favorable results secured at the present time in gunshot injuries of joints. Penetration, with little or no fracture, was more often noticed in gunshot wounds of joints in civil practice now than formerly; in other words, the harder lead bullet of revolvers of to-day made a more humane wound than did the weapon of a generation ago. The lead used forty years ago or so was so soft that when the bullet struck a resistant bone—as, for example, the tibia or femur—the ball was apt to flatten against the bone. In some extensive tests that Major LaGarde was now making with revolvers and pistols of all kinds and calibers, the projectile was found to make a perforation in the joint-ends of bones very much like that produced by the bullet now used in the military rifle. A great deal of the favorable outcome from joint wounds, especially, came from the hardening of the lead by the admixture of 5 per cent. of antimony. We were apt to say to-day that everything depended upon antisepsis; a great deal certainly did depend upon this, but a great deal also depended upon the difference in the lesions. The three important factors to be considered in gunshot wounds of the diaphyses and epiphyses of bones were: (1) resistance of impact; (2) sectional area of the bullet, and (3) the velocity of the bullet at the time of the impact.

Wounds of the Chest.—Chest wounds were classed among the humane wounds to-day. Penetrating gunshot wounds of the chest gave a mortality of 62.5 per cent. in the Civil War as against 27 per cent. in the Spanish-American War, and the reports from South Africa showed that these injuries were the most hopeful of the whole series of trunk and visceral injuries. The treatment consisted in removing loose fragments of bone, the application of a clean dressing and the securing of quiet. The value of the latter was especially shown in military practice, where often the exigencies of a campaign demanded the transport of the wounded before the wounds had fully healed. Under such circumstances hæmothorax and pyothorax were noted in as many as 90 per cent. of cases in some of the recent wars. As long as the men were near the base hospitals, and it was not necessary to transport them very far, they did beautifully, but as the distance over which the wounded had to be transported increased the results became poorer, until finally, as before stated, 90 per cent. showed these complications.

Wounds of the Abdomen.—Under the best conditions the mortality from gunshot wounds of the abdomen in civil practice was 53.8 per cent., whereas in military practice this mortality varied between 70 and 100 per cent. When laparotomy was attempted in military practice the result was nearly always fatal. Of three cases operated upon in the Santiago campaign the mortality was 100 per cent. The greatest difficulty in field practice was the environment. At present the policy of non-interference was preferred by military surgeons during an active campaign. Some remarkable recoveries occurred in the Spanish-American War from penetrating wounds of the abdomen, and these were attributed to the fact that the men had been fasting for a long time before. Commenting upon this, the speaker said that when there was much fluid in the alimentary tract the destructive effects of penetrating gunshot wounds were very great indeed.

In military practice the removal of lodged missiles was forbidden during the stress of an active campaign. An operative wound to remove a ball at such times meant additional risks from sepsis. It was far different in civil practice, and, hence, it was wise to remove the ball as soon as it had been accurately located by the Röntgen ray. Thanks to antisepsis and the Röntgen ray, the remote and ulterior consequences of gunshot wounds had been reduced to a minimum. Formerly, one-half of the misery and suffering after injuries in war were due to the dead bone or the lodgment of various extraneous matter in the wounds. The absence of sepsis precluded necrosis, so that the only remote effects now were in connection with parts, the injury of which produced a loss of function.

Special Factors in the Civil War.—Dr. ENOCH V. STODDARD of Rochester, N. Y., opened the discussion. He said that the changes in military arms had given rise to certain definite eras in military surgery. During the War of the Revolution there was very little time spent in malarious sections, whereas during the Civil War a very large proportion of certain campaigns was spent in and about sections of the country in which the land was water-soaked and miasmatic influences were common and potent. Little or no reference had been made to this in Dr. Stephen Smith's paper. His own experience in the war covered three years, from 1862 to 1864. During the first part of this time he was in the hospital service; hence, the conditions observed at that time were secondary, and the operations were likewise secondary. There were many cases of hospital gangrene, and this he attributed not alone to lack of cleanliness and to imperfect methods, but to the fact that the men first going into the field were raw recruits, coming directly from civil life without previous training. As the troops became seasoned, it was the common experience of the surgeons that the wounded men did better. In 1863 and 1864 he saw only active service in the field. He had been struck by the absence of all reference to the materia medica, except in the first paper. Quinine was used very largely in the campaign of 1863 and he wished to say a strong word in favor of the British surgeons' advocacy of Peruvian bark. This was a complex substance, and he had used preparations of this bark very freely. He had found a tincture of this bark, combined with aromatics, much better than quinine itself. He would not be willing to go into the field without Peruvian bark, opium, and similar standard drugs, no matter how excellent the purely surgical equipment.

Use of Tetanus Antitoxin.—Dr. ALEXANDER LAMBERT said that in 1900, just before the Fourth of July, tetanus antitoxin had been sent by the Board of Health to the dispensaries, with the recommendation that 10 c.c. should

be given to every one coming in with a toy-pistol wound. The result was that no case of tetanus was reported as having developed at that time from these injuries. The dose should be 10 c.c. in ordinary cases, and this should be administered as soon as possible after the receipt of the wound. In a part of France in which tetanus was very common, all persons presenting sloughy wounds were injected with the tetanus antitoxin, with the result that the disease was wholly prevented. When the symptoms of trismus developed it was not the beginning of tetanus, but the beginning of death, and consequently this was too late to give the tetanus antitoxin with any hope of very good results.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 13, 1904:

	Cases.	Deaths.
Measles	721	14
Diphtheria and croup	327	56
Scarlet fever	346	30
Smallpox	...	...
Varicella	110	...
Tuberculosis	264	142
Typhoid fever	24	4
Cerebrospinal meningitis	2	...

The Influence of Oxygen Taken by Full Normal Respiration, or Chemically Pure, as a Means of Sustaining and Increasing Mental, Nervous, and Physical Energy.—Cordelia A. Greene declares that there is no more valuable means of stimulating the flagging nervous energies than by the use of oxygen. One of its first effects is to make the brain and arterial pulsations more full and normal. It has proved very useful in enfeebled heart action, in hysteriform seizures, in cases of ordinary or very serious forms of lobular pneumonia, also in certain nervous types of asthmatic difficulty when no organic change exists. One of the most important effects of oxygen is to stimulate the vasomotor nerve centers and acting through the pneumogastrics to their peripheral terminals, to have direct mechanical and functional influence upon the air cells. In the inhaling room the air should be perfectly fresh and not above 65°. After each inhalation the patient should be directed to make ten full, strenuous, nasal respirations, as in smelling, breathing noiselessly but more deeply each time. The effort of inhalation of oxygen should be made a little more intently, until from ten to fifteen full inhalations are taken. After the patient can fill the air vesicles fairly well, ten or twelve inhalations will be quite sufficient at one sitting. The patient should spend the best strength possible to secure full nasal respiration, whether in exercise or rest. Oxygen quiets the nerves and puts the patient into a restful condition. Enforced nasal respiration, from two to four hours of the day, sitting or lying in the open air, should be earnestly enjoined upon all patients showing pulmonary or nervous weakness. In any case of respiratory obstruction, the value of oxygen is far greater than that of any form of alcohol, for it stimulates the brain and respiratory functions normally. In those leading a sedentary life, there is generally a partial suspension of respiration from nervous preoccupation, resulting in scanty brain oxygenation. This gradually leads to neurasthenic conditions. The inhalation of oxygen in the pure air, by normal respiration or its medical administration, promotes sleep and compels equilibrium of the nerve currents. In cases of hyperæmia, oxygen is valuable. In treating alcohol and opium habitués, oxygen is most beneficial. Oxygen quickens the functions of waste and enters largely into the healthful building of all the bodily tissues.—*The Woman's Medical Journal.*

Honors for a Country Doctor in England.—Among the recipients of the King's birthday honors in England, occurs the name of Dr. Alan Reeves Manby of East Rudham, Norfolk, who was knighted. Sir Alan Manby's career has been one of much interest, and something of an inspiration to country medical practitioners in Great Britain. The new knight has been during his whole professional life a country doctor, living in a village in a purely rural district. For about twenty years Sir Alan Manby occupied the position of surgeon-apothecary to the Prince of Wales, whose country seat was in Norfolk, and when the Prince became King, the Norfolk general practitioner was given the same post in the royal household, as well as being made surgeon-apothecary to the present Prince of Wales. Sir Alan Manby accompanied the Prince of Wales on his extended tour to the British colonies and possessions in the capacity of medical attendant.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 13, 1904:

THE SURGICAL TREATMENT OF FACIAL PALSY, WITH THE TECHNIQUE OF FACIO-HYPOGLOSSAL NERVE ANASTOMOSIS.*

BY ALFRED S. TAYLOR, M.D.,
NEW YORK,
VISITING SURGEON TO RANDALL'S ISLAND HOSPITALS; ASSISTANT INSTRUCTOR IN OPERATIVE SURGERY, COLUMBIA UNIVERSITY.
AND
L. PIERCE CLARK, M.D.,
NEW YORK.
VISITING NEUROLOGIST RANDALL'S ISLAND HOSPITALS; CONSULTING NEUROLOGIST MANHATTAN STATE HOSPITAL; ASSISTANT AT VANDERBILT CLINIC.

THE nature of the lesions of the facial nerve causing its paralysis are so generally and well understood, that it is not necessary to make extended comment upon them.

The painful deformity resulting from chronic palsy; the liability of injury to the eye of the corresponding side; the interference with the usefulness of the mouth from the early paralysis or from the late contracture and spasm of the face muscles, should warrant any reasonable attempt to mitigate or cure the condition by surgical procedure.

During the last decade much experimental and some clinical work in nerve suture and anastomosis has been done by Kennedy, Faure, Manasse, Barrago-Ciarella and Breavoine, in which it has been demonstrated that when the peripheral end of a divided motor nerve is sutured to the proximal end of a neighboring motor nerve, the paralyzed muscles ultimately regain their coördinated function. A similar result follows the lateral implantation of the peripheral end of the nerve into the trunk of a neighboring motor nerve. Upon these facts is based the surgical treatment of chronic facial palsy.

The first method attempted was that of faciospinal accessory anastomosis, in which a portion or the whole of the spinal accessory nerve was divided at its entrance into the sternomastoid muscle, turned upward and sutured to the peripheral end of the divided facial nerve. There were developed four modifications of the faciospinal accessory anastomosis. (1) The division of a part or the whole of the spinal accessory and the making of an end-to-end anastomosis with the facial. (2) The implanting of the facial into the side of the spinal accessory which was split longitudinally. (3) The implanting of the facial into the spinal accessory, the latter partially cut transversely. (4) The implanting of the part of the accessory into the facial, end to side. The operation of faciospinal accessory anastomosis was first performed on man by Ballance[1] in 1895, three years later by Faure[2] (Hopital Laennec), still later, in 1899, by Kennedy[3] at Glasgow,† and finally by Cushing[9] of Baltimore, in 1902. In the same year Hackenbruch[8] (Wiesbaden) implanted two-thirds of the spinal accessory into a slit in the facial trunk after a palsy of seven and three-quarter years' duration, with marked improvement as a result.

This operation in itself is comparatively simple, but a more or less permanent paralysis of the trapezius and sternomastoid muscles results, which is proportionate to the amount of division of the spinal accessory nerve. As nerve regeneration takes place the face becomes symmetrical and its muscles move once more with good coördination. However, a sudden voluntary movement of the face is nearly always accompanied by a distressing and unsightly involuntary movement of the shoulder, and vice versa, as shown in Cushing's series of illustrations in the *Annals of Surgery*, May, 1903. Inasmuch as the accessory non-volitional movements were so undesirable, search was made for some other convenient source of motor supply for the palsied facial nerve. The hypoglossal was then selected, as it was a pure motor nerve, running near the facial and supplying groups of muscles intimately associated anatomically and physiologically with those supplied by the facial. Cases of this type have been reported by Ballance and Stewart,[1] Körte[10] and Frazier.[11]

The operation is indicated in all cases of palsy of the facial nerve from a lesion of the nucleus within the brain or of the nerve trunk on the base of the brain and in lesions of the nerve following operation for mastoid disease, as recovery from these affections is rare. It is justifiable in Bell's palsy when there is complete reaction of degeneration of the facial nerve after several months of faithful treatment, and there is no indication of volitional return of nerve power.

We now know definitely that a paralysis which affects all the branches of any peripheral nerve must be due to an affection of the trunk of that nerve. There is no evidence at any rate that cold ever paralyzes the intramuscular nerve-endings. The lesion in Bell's palsy is a neuritis, and is situated in all probability within the fallopian canal. In such cases existing for several months, recovery occurs in part only, if at all, especially in advanced life. Even in nerve degeneration lasting a month, some trace of the palsy and some atrophy usually remains permanently (Gowers).

In all severe cases contractures of the muscles occur and, in some, spasm is superadded when there is only a slight return of power. The possibility of a return of power in long-standing cases should not be judged solely by the muscle movements about the eye or angle of the mouth, as the muscles responsible for the former are probably supplied by the third nucleus, and the latter by the twelfth nucleus. The facial (seventh) extends down nearly to the level of the hypoglossal (twelfth) nucleus. The very close physiological relationship between the muscles of the lips and tongue is probably due in no small part to the anatomic fact of the close connection of the two nuclei. Fibers have, indeed, been traced from one nucleus to the other by way of the posterior longitudinal bundle. If the nerve fibers supplying the angle of the mouth do not originate from the twelfth nucleus, movements of the tongue and the orbicularis oris are at least coör-

*Presented to the Surgical Section of the New York Academy of Medicine, January 8, 1904.

†Hartley of New York did one operation of this character in 1900 (oral communication)

dinated through the agency of the hypoglossal nucleus, as has been suggested by Mendel, Tooth, and Turner. Moreover the nerve fibers supplying the orbicularis palpebrarum originate in the third nucleus and course in the trunk of the seventh nerve to their destination in the muscles. Therefore the best test of the degree of recovery is the amount of return of power in the zygomaticus major muscle, which elevates the angle of the mouth, and which is innervated only from the seventh nucleus.

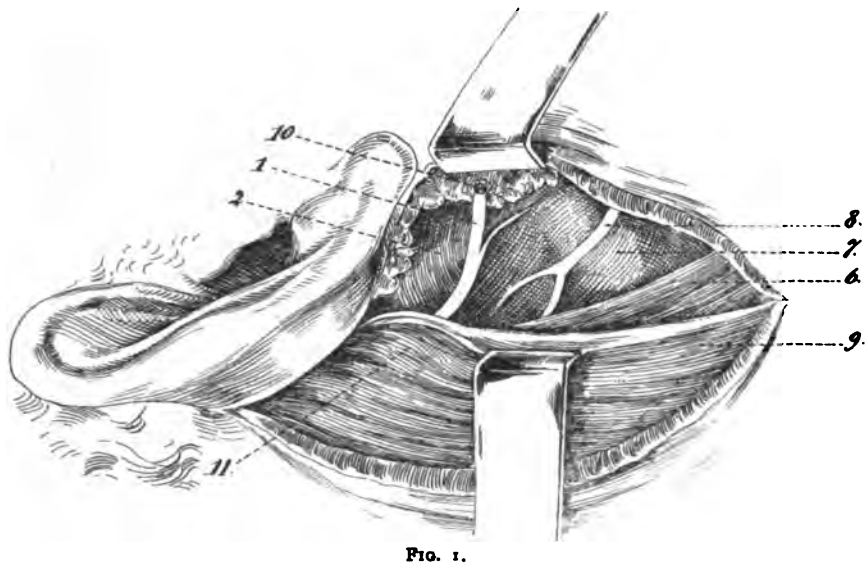

FIG. 1.

1. Facial nerve; 2. styloid process; 3. internal jugular vein; 4. hypoglossal nerve; 5. pneumogastric nerve; 6. posterior belly of digastric muscle; 7. transverse process of atlas; 8. occipital artery; 9. sternomastoid muscle; 10. parotid gland; 11. mastoid process.

With the foregoing in view the following three cases of facial palsy were selected:

CASE I.—Jerry M., six and one-half years old, had scarlet fever in the early summer of 1903, followed by otitis media and mastoiditis, for which operation was done July 13, at Randall's Island Hospital. Three days later, facial palsy appeared and rapidly progressed to complete paralysis. October 24, 1903, three and one-half months later, complete R. D. was found on electrical examination. Facio-hypoglossal suture was at once done under chloroform anæsthesia. The facial nerve was soft, friable, and gray in appearance. But one suture could be made to hold it to the hypoglossal, which in turn was under such tension that a fine suture was passed through the hypoglossal sheath to anchor the nerve to neighboring fascia and so prevent tension on the anastomosis as far as possible. Primary union of the wound was obtained. There was almost complete palsy of the muscles supplied by the hypoglossal immediately after operation. Ten weeks after operation some difficulty of speech remains, owing to imperfect use of the tongue. Difficulty in swallowing, mastication, and a unilateral furring of the tongue, all of which were present for some weeks after the operation, have disappeared (operative injury to twelfth nerve). The face is far less asymmetrical and the eye can be partly closed, but the patient has no power over the face; R. D. persists unchanged as yet The prognosis as to complete recovery in this case is doubtful; the nerve had, at the time of operation, already undergone marked degeneration. It must have atrophied nearly down to the muscles. We look, however, for a decided return of power after six months or a year, which is approximately the amount of time necessary to bridge the gap between the good nerve-ending at the muscle and the hypoglossal implantation.

CASE II.—Betsy G., forty-five years old, married, three children, no miscarriages. In August, 1903, she had severe pain in the right ear for two days preceding sudden complete paralysis of the right side of the face. Under electrical, massage, and bath treatment for three months there were no signs of spontaneous recovery. Electrical examination showed reaction of degeneration from the beginning. November 28, 1903, ether was given and the operation was performed; primary union resulted. In this case the anastomosis was readily made without tension on the nerves. From manipulation of the hypoglossal nerve, however, considerable temporary paralysis resulted. There was some interference with swallowing, mastication and speech for several weeks. Now, six weeks after operation, these difficulties have entirely gone and the changed electrical reactions show beginning union at the nerve anastomosis and regeneration in the facial. The patient still complains of some pain in the shoulder, side of the neck, and in the external ear, the cause for which is difficult to explain.

The prognosis as to ultimate complete return of power in this case would seem to be good. The amount of constant current necessary to awaken

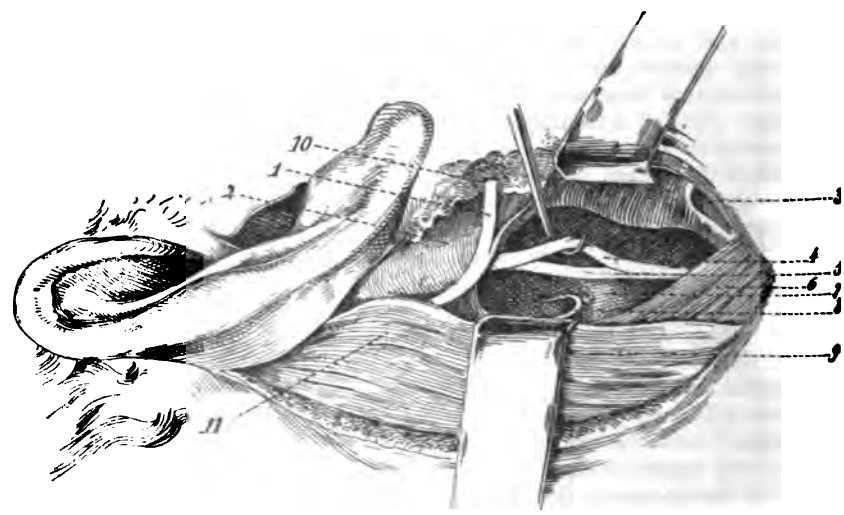

FIG. 2. The structures are numbered the same as in Fig. 1.

movements in the face through the hypoglossal facial trunk is steadily decreasing, although reaction of degeneration still remains. The latter will, however, begin to change after several months of repair and treatment. The early electrical test of nerve repair at the point of suture is of great practical importance.

CASE III (by courtesy of Dr. Weir).—Lillian M., aged twenty-six years, married, no children and no miscarriages. Facial palsy followed a mastoid operation eighteen months ago. There

was no return of power. The faciohypoglossal anastomosis was done by Dr. Weir at Roosevelt Hospital, December 22, 1903, by the method described below. Considerable palsy of the hypoglossal resulted from operative trauma, but at the date of the present report (January 20) it is much diminished and bids fair to decrease as rapidly as that in Case II.

This method of faciohypoglossal nerve anastomosis is the result of numerous dissections on the cadaver, and has been applied very satisfactorily in the three cases detailed in this paper.

The operation involves the following steps: (1) the incision; (2) the isolation and section of the facial nerve; (3) the exposure of the hypoglossal nerve; (4) the implantation; (5) the closure of the wound; (6) the after-treatment.

1. The patient is etherized; a firm cushion is placed behind the head and neck; the head is turned slightly to the opposite side and extended a little upon the neck; the operative field is thoroughly cleaned. The incision involving the skin and subcutaneous tissues passes along the anterior margin of the mastoid process and the sternomastoid muscle for about 5 cm. (2 in.), starting at the level of the external auditory meatus. The temporofacial veins may or may not be disturbed.

2. The deep facia is divided in the same line with special care to keep close to the anterior border of the mastoid process to avoid damage to the parotid gland. This gland, covered by its capsule, is separated from the mastoid by an elevator and held forward by a blunt retractor, exposing the posterior belly of the digastric muscle, which is often pulled downward and backward. When the digastric is large it may be necessary to divide its upper border transversely to its long axis to allow the retractor to give a proper exposure of the field.

In cases in which the mastoid has previously been operated upon the bony landmarks are often confused and the scar tissue interferes somewhat with the easy performance of the first stage of the operation. Under such circumstances the incision is made along the anterior border of the bony remnant of the mastoid, and, keeping just behind the parotid gland, the dissection is carried through the scar tissue till the deeper landmarks (the digastric muscle and the styloid process) are identified, when the operation proceeds as before.

3. The isolation of the hypoglossal nerve is the most difficult and tedious step and involves whatever danger there is in the operation. The finger in the wound readily identifies the prominent smooth transverse process of the atlas. (Fig. 2, No. 7.) Not infrequently the occipital artery runs upward and outward across the anterior surface of this prominence. It should always be looked for, and when present, either displaced outward, or divided between two ligatures, as an unexpected division of it gives rise to annoying hemorrhage and blurs the anatomical field.

Lest they be inadvertently damaged in the following steps of the operation it should also be remembered that over this same transverse process, but more toward the median line, the spinal accessory nerve runs obliquely downward and outward (sometimes in front of, sometimes behind the internal jugular vein), while the internal jugular vein runs vertically in front of it. These two structures are covered by a layer of deep cervical fascia, through which a vertical incision is made over the outer border of the transverse process and is continued upward and downward till it is about 4 cm. (1½ inches) long. Through this slit in the fascia the internal jugular vein is exposed and is separated posteriorly by blunt dissection. The spinal accessory nerve should not be disturbed during the operation. The fascia and vein are then retracted forward and inward by a blunt retractor. Imbedded in the connective tissue thus exposed in the depth of the wound are seen two white cords, the hypoglossal and pneumogastric nerves, with the internal carotid artery pulsating just to their inner side. (See Fig. 2.)

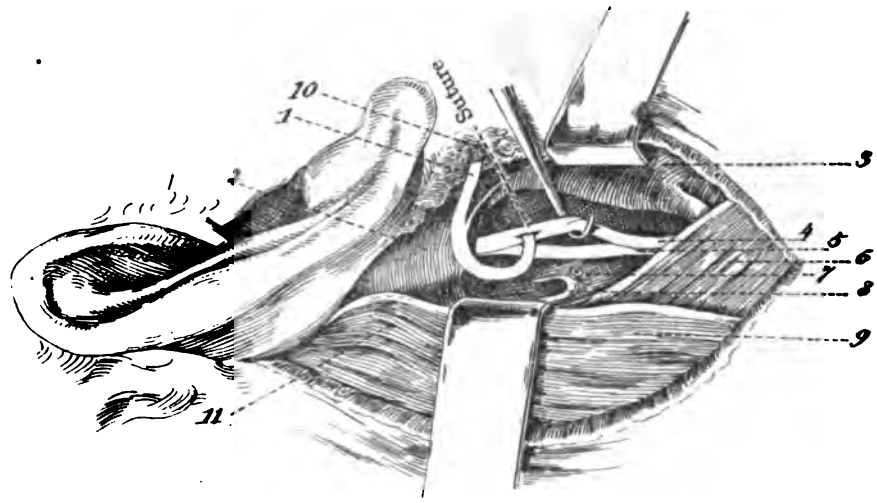

FIG. 3. The structures are numbered the same as in Fig. 1.

The index-finger pushed into the depth of the wound and slightly forward, readily identifies the styloid process. Near the base of this process the trunk of the facial nerve passes almost directly forward to enter the parotid gland, and it can usually be felt to roll as a distinct small cord, surrounded by connective tissue, between the finger and the styloid process. (Fig. 1.) When there is difficulty in identifying it in this manner one should remember that it emerges from the stylomastoid foramen, which is just behind the base of the styloid process.

The nerve once identified is enucleated from the surrounding connective tissue, and is divided as far up the stylomastoid foramen as a narrow-bladed sharp knife will allow. Usually one can get from 1 to 2 cm. (½ to 1 inch) of free nerve trunk.

At this point it is desirable to prepare the nerve for the final suture. About a quarter of a centimeter (⅛-inch) from its free end, two fine silk sutures are passed through the nerve sheath on opposite sides of the nerve and each tied in a square knot. The ends are left long (15 to 20 cm., 6 to 8 inches). (Fig. 4—A.) The nerve end is trimmed to a wedge shape with a sharp scalpel. The sutures and nerves are protected from damage during the next step.

Usually the more superficial of the two nerves is the one sought. It must be positively identified however. Mechanical or electrical stimulation will cause its proper muscles to contract (styloglossus, hyoglossus, geniohyoid, geniohyoglossus, thyrohyoid, sternothyroid, sternohyoid) or one may follow its course anatomically downward, to the point where it turns forward, around the occipital

artery and gives off the descendens hypoglossi nerve.

Once identified, it is dissected upward till the stump of the facial can be approximated to it without tension. This must be done with care not to divide the communicating branches from the pneumogastric, upper ganglion of the sympathetic and the two upper cervical nerves, all of which are in the immediate neighborhood.

4. While the nerve is supported on a blunt hook

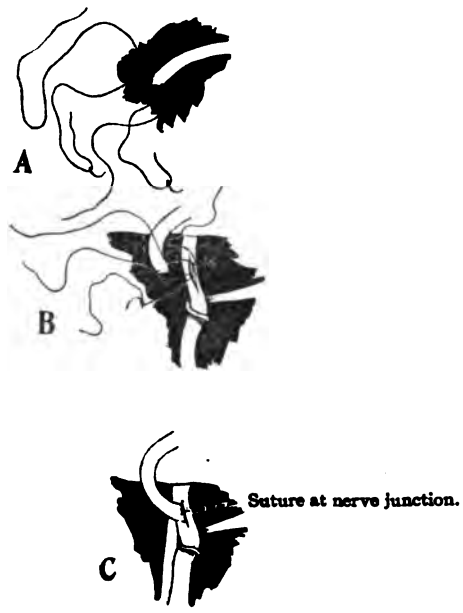

FIG. 4.

a longitudinal slit ½-cm. (¼-inch) long is made well into the nerve trunk. A fine curved needle is threaded on to one of each pair of long silk ends previously left tied to the stump of the facial nerve. One suture is passed through the inner and the other through the outer margin of the wound in the hypoglossal nerve. When the sutures are tied the wedge-shaped end of the facial is snugly held in the cleft in the hypoglossal nerve and is usually best turned slightly upward by means of a probe, a procedure suggested by Dr. Weir. These sutures must not be tied too tightly lest they injure the fibers of the hypoglossal nerve, a few of which are almost surely included in their grasp. (Fig. 3 and Fig. 4—A, B, and C.)

To prevent the ingrowth of connective tissue elements, Cargile membrane is wrapped about the nerve junction. The hypoglossal is dropped back to its normal position, and there is usually no tension on the sutures.

5. If the digastric muscle has been partly divided it should be sutured with catgut. No other deep sutures are required, since the parts naturally fall back into position. The skin is closed with silk sutures. No drainage is used. Sterile dressings are applied. Fixation of the head and neck are, as a rule, not necessary.

6. The after-treatment is a most important factor in obtaining the desired result. Massage, electricity and, later, coördinated muscular movements, based upon certain principles, must be persistently and systematically resorted to for months. It is now well recognized that after any nerve transplantation, the return of coördinated power involves a reëducation of the nerve centers, both in the spinal cord and in the cerebral cortex.

The education of the spinal centers progresses fairly rapidly, while that of the cortex requires long periods of time, often years, for its completion.

Experimental work on animals has shown steady progress in return of function for periods of five to ten years.

As soon as voluntary power over the muscles begins to return, the patient should be taught systematic exercises for the development of muscle power and coördination. The cortical volitional impulses thus sent down, far surpass in value either electricity or massage as a stimulus to nerve and muscle regeneration.

The result of the operation will depend upon a number of conditions.

1. The best results follow in those cases in which the cause of the paralysis has been a traumatic division of the nerve. Less hopeful of complete recovery are those cases due to neuritis, especially when suppurative in character, *i.e.* in suppurative mastoiditis.

2. The longer the time between the paralysis and the anastomosis, the slower and less complete is apt to be the recovery. In cases of traumatic paralysis anastomosis should be immediate. In interstitial neuritis (Bell's Palsy) it is necessary to wait a few months for signs of spontaneous recovery which often occurs. At the end of three to six months' treatment the neurologist can decide the propriety of operating. In the suppurative forms operation should be done as soon as the danger of infection in the wound is passed, as there is small likelihood of spontaneous recovery.

3. The condition of the paralyzed muscles, flaccidity, contracture, spasm, changes in electric reaction, and, most particularly, the degree of atrophy, is important. The more atrophy the less hope. Therefore massage and electricity must be systematically used from the onset of the paralysis to keep the muscles in good condition in case either spontaneous regeneration of the nerve occurs, or operation becomes necessary.

4. The technique must be precise and delicate

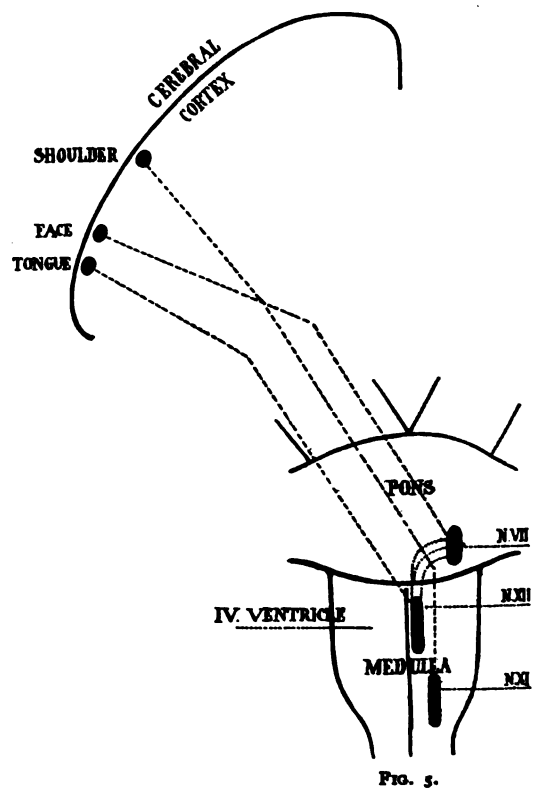

FIG. 5.

The nerves must not be pinched or unduly handled the sutures must be fine, and involve only the nerve sheaths. The importance of these details is accentuated by the postoperative appearance, in each of the three cases cited above, of temporary interference with the functions of the hypoglossal nerve. The degree and duration of this interference was directly proportionate to the traumatism inflicted on

rve during operation. There must be the least sible amount of scar tissue. Asepsis is essential, suppuration, aside from being dangerous in itself, uld reduce the probability of nerve union to minimum and there would later be pressure the nerve due to contraction of the cicatrix.

. The importance of the after-treatment has been icated above. The first degree of recovery con- s in symmetry of the face during quiescence, but hout volitional control over the muscles. The t degree consists in the return of volitional con- of the muscles, but with the paralyzed side of the uninfluenced by the emotions (laughing, cry- etc.). The third and complete degree consists he return of emotional control of the face.

his was acquired to a certain extent in Körte's e." The reasons, referred to early in the paper, preferring the hypoglossal to the spinal-accessory ve as a medium for anastomosis, are rendered e intelligible by Fig. 5, which represents schem- ally the sharp contrast between the close rela- ship of the nuclei of the facial (seventh) and oglossal (twelfth) nerves, and the wide interval ween the facial and spinal accessory nuclei. in the face and tongue centers in the cortex are ely associated, indeed overlap, while the face shoulder centers are widely separated, a fact hasized by Ballance and Stewart.

he physiological association of the two nuclei he medulla is strikingly shown in the frequent ction of both in disease, as labioglossal palsy, by the fact that the transverse fibers of the ue and the orbicularis oris can contract only ther. The close anatomical connection of all cranial nerves through the posterior longitudinal ile should be considered in the light of a rudi- tary plexiform arrangement analogous to that he cervical, brachial, and crural plexuses.

his close association of the cortical and medullary ers of the facial and hypoglossal nerves renders process of reëducation (previously discussed) ter and simpler than in the case of the spinal ssory.

it be granted that the hypoglossal is the pre- d nerve, there arises the further question as hether it should be completely divided and then ed end to end with the facial, or whether the al should be implanted laterally into it.

razier[11] divided the nerve below the posterior y of the digastric, over which he turned it up did an end-to-end suture with the facial.

he reasons for the method were that:

. The operation (end-to-end suture) is easier.

. The reëducation of the cortical center is easier has only the new group of muscles to work on.

. End-to-end suture causes more active nerve neration.

. If the result will probably be more complete, the nerve should be divided, because "paralysis he tongue and other muscles supplied by the oglossal is, relatively speaking, trifling."

hile the end-to-end suture undoubtedly gives the t active and complete nerve regeneration, yet felt scarcely justified in causing a permanent alysis and atrophy of its muscles, by complete ision of the hypoglossal.

The difficulties in mastication, deglutition, and onation, present for the first few weeks in our ree cases were of sufficiently marked degree to use us to feel that the complete and permanent ralysis following transverse division of the nerve ould be a serious drawback to the comfort and ppiness of the patient. Case II could swallow ly liquid food for three weeks after operation.

In Case No. I the boy's voice for several weeks sounded like that of a cleft palate, and many of the guttural words could scarcely be enunciated. Only three cases besides those in this paper are recorded, and they are all of such recent date, that the ultimate results are still problematical. A larger number of cases and a sufficient lapse of time, so that final results can be compared, will give us a reasonable basis for determining whether the patient is better off with a more complete return of power in the facial supply with permanent paralysis of the hypoglossal, or whether, on the whole, he is better off with a somewhat less complete control of the facial and only a temporary disturbance of the hypoglossal.

It seemed to us, meanwhile, the part of conservative surgery to approach the subject from the standpoint of doing as little additional damage to the patient as possible until we could see what was to be the result.

QUESTIONS OF URANALYSIS BEARING UPON THE DIAGNOSIS OF CONTRACTED KIDNEY*

By BEVERLEY ROBINSON, M.D.,
NEW YORK.

For many years past I have been especially anxious at times about:

First, patients whom I *believed* were suffering from symptoms of uncomplicated contracted kidney.

Second, patients whom I *suspected* had contracted kidney, adjoined to neurasthenia or other disease.

Third, patients, women particularly, whose uranalysis has not shown other evidences of contracted kidney than continued low specific gravity and deficient excretion of urea.

In the first category, I place patients over forty years of age who, with manifest changes in heart and arteries, show urine in large quantity, of very pale color, low specific gravity, with deficient elimination of urinary solids (mainly urea), and traces or small amount of albumin, and few or many granular and hyaline casts. Whenever these patients take cold and begin to void a relatively small quantity of urine, or if after exposure, fatigue, or imprudences in diet, they suffer from nervous disturbances, nausea, vomiting, etc., I have considerable anxiety until these symptoms disappear, not knowing whether an explosion of threatening nature might proceed from the kidney at any moment by reason of its functional inadequacy.

*Read at a meeting of the Practitioners' Society of New York, January 8, 1904.

In those instances in which I am doubtful in regard to the renal condition present, viz., women of full or spare habits, near the menopause, who have born several children, or who from other causes have had a life full of worry, fatigue, hardship, etc., nevertheless show no cardiac enlargement and no tactile arterial thickening, and who occasionally, with constipated bowels or nervous break-down, have increased arterial tension, accentuation of second aortic sound, some uræmic symptoms with rapid dimunition in quantity of urine, which with low specific gravity and low output of urea does not contain albumin or casts. The diagnosis in these women remains doubtful as to what should be assigned to neurasthenia, and what to contracted kidney; and during twenty-four or forty-eight hours I have occasionally been much worried as to the outcome of morbid symptoms. With rest in bed during a few days, free movements from the bowels, liquid diet, and later or at the time of the attack an appropriate cardiac tonic or stimulant, such instances have cleared up, and anxiety is relieved until another outbreak occurs, which may not be in months or in years. Such attacks are caused by renal inadequacy—but behind the mere functional loss of power probably exists the contracted kidney.

In the third class it is almost impossible at times to say whether or not the patient is merely a sufferer from nervous functional disorder, inasmuch as anæmia or irregular gout may be present. Usually there are practically no characteristic features shown by careful examination of the urine. There may be, however, from one cause or another almost complete suppression of urine during twenty-four or forty-eight hours, with or without uræmic symptoms, such as twitchings, headache, nausea, etc. Such cases are on the border line, so to speak, of functional and organic disease. If the kidneys could be examined they might show interstitial changes.

On the other hand, during life they give no more evidence of them than may be discovered in many a girl of twenty who is simply nervously tired and anæmic owing to late hours and too many social engagements. The difference of age is what in the one case gives anxiety, and in the other brings relief to the mind, for after all it is most exceptional to have contracted kidney in youth under the conditions referred to.

In cases of undoubted contracted kidney we may have had urine which is thoroughly characteristic of this form of disease, and with the urine we may have had other typical signs and symptoms. Subsequently, while heart and arteries show interstitial changes unquestionably, the urine may become so modified from its examination alone it would be impossible to make an accurate diagnosis of the case. For example, the urine may be of normal or high specific gravity, eliminated in fair quantity, with abundant urinary solids and containing no albumin and no casts. In some of these cases at this period the deposit of urates or uric acid is very considerable and despite the fact that the diet has been carefully regulated. Such cases, usually, are gouty or lithæmic in origin, and such dyscrasia we can rarely, if ever, wholly eliminate.

To sum up what I would say about the classes of cases described, I would add that in certain instances *urinary analysis* alone will not enable us to make an exact diagnosis, and in every case, almost, it is desirable fairly and exhaustively to consider *all other clinical signs and symptoms*, and even then at times we shall find it difficult or impossible to pronounce ourselves in exact and positive terms about a given case.

I would like also to say a few words about cases of contracted kidney complicated with acute disease. In some of these the outlook seems very serious occasionally, if mere laboratory reports of uranalysis be considered. But if with these grave reports the general symptoms are relatively favorable, I have reached the conclusion that the prognosis is not invariably very threatening from the renal standpoint, and that eventually the patients will recover or return at least to the condition of kidneys which existed prior to the acute disease.

This statement I have verified very lately in typhoid fever. If the quantity of urine voided in the twenty-four hours is sufficient, and if we are looking after the primary acute disease rationally and with due consideration for the individual factors in each separate case, we shall have rarely occasion to dread the immediate renal condition. And while it is true in cases of contracted kidney that a low output of urea with some persons is always to be regarded as a danger signal, on the other hand, such condition may occur to an excessive degree at times and not be followed necessarily with acute manifestations of grave import, and may indeed be compatible in less degree, with many years of life, if carefully and judiciously watched and treated.

The foregoing remarks are the outcome of continued observations of numerous cases in which I have had the expert help of well-known and reliable chemists and microscopists.

Finally, I would say that I am of the opinion that not infrequently the primary form and the arteriosclerotic form of contracted kidney described by authors are essentially one and the same anatomically, and satisfactory explanation of different urinary signs at various stages of the disease remain to be given.

THE HOT FULL-BATH.*

By FRIEDRICH GROSSE, M.D.,
NEW YORK.

THE hot full-bath, as a well-defined conception, was introduced into the physician's armamentarium by Baelz,[1] in a paper read at the Twelfth Congress for Internal Medicine, held in Wiesbaden in 18[illegible]. Though hot baths had been applied before, such instances occurred without any positive indication; in fact, it was often merely by accident. Even to-day the terms "warm" and "hot" are used indiscriminately, not only by laymen and physicians, but even by specialists in hydrotherapeutics, when the full-bath is in question. In former days even experimental efforts ceased at 104°, so that most of the data in regard to "hot" baths, when they are not accompanied by more definite statements in regard to duration of the bath and the degrees of temperature, are not always useful. Following Baelz's suggestions numerous authors have discussed the question, but the results of their labors are widely scattered in the literature of medicine. For this reason a certain confusion has arisen within this domain, so that even textbooks on hydrotherapy often treat of the warm and the hot full-bath in the same chapter, and then it happens that an assertion relating to the one is made to apply to the other without sharp discriminating, and yet the same distinction should be made as sharply as between a neutral and a cold bath.

While the limits for the neutral or indifferent bath are everywhere positively announced as lying between 93 and 98.5° we find absolute anarchy prevailing beyond blood temperature.

Kellogg,[2] in his excellent textbook, calls a bath 98.5°-104° F. hot; Matthes,[18] and Raymond (Phy-

*Read before the German Medical Society of New Yo[illegible]

ology) call one of 98.5°-113° F. hot, and Bottey[1] calls from 98.5° up *très chaud*. Baruch[2] sums up all these baths under the general title warm baths, while calling those above 104° hot. Kellogg terms these very hot. Baelz defines a bath of 104° F. moderately hot, and from 108° up very hot. It must be clear also that when one refers to a duration of 2 to 10 minutes, another one of 5 to 15, and still a third one up to 60 minutes, the results must be widely different.

It may be granted that in some respects we attain the same effects with a bath of longer duration and lower temperature as we do with one of higher temperature and shorter duration, but nevertheless there is a long series of phenomena to be considered in the hot bath that are not observable in the less warm bath.

If we further remember how difficult it is for those less experienced properly to choose, for any special case, the duration of the bath from the data contained in the literature on this subject, it would seem desirable to define the conceptions more simply.

Baths from 98°-102° may be of moderately long duration before inducing heart troubles, but a bath of 106°-107° should not last longer than fifteen minutes, and those above that not longer than ten minutes.

Baths from 98°-102° approach the neutral in their effects, inasmuch as they still exert a certain sedative influence, while the second group produces entirely different phenomena, the result there being positively exciting. Therefore, it might be well to define 98°-100°, and perhaps even 102°, simply as warm, and those ranging from a temperature of 106° upward unqualifiedly as hot. If these terms were adopted the very name of the bath would at once suggest the boundary to be set for the duration and the physiological effects that would become pronounced. To differentiate according to Baelz, "moderately hot" and "very hot" has already been proven impracticable, because these terms have not become established in the literature.

Baelz, in his data, has reference always to baths as hot as possible, such as are customary among the Japanese, but the limit of endurance with us seems to lie between 109°-110° and a duration of 6, 8 to 10 minutes, which on the one hand should always suffice to produce the desirable effect and on the other, with some care, should never bring about undesirable eventualities. Therefore, we may use the term "hot bath" as denoting a bath of 107° or more and of a duration of 6 to 10 minutes, and such a bath deserves much more careful attention on the part of physicians than has been the case hitherto. Baelz has already given utterance to this thought, and the writings that have appeared since then confirm it. Whoever has once become familiar with this bath will often resort to it not in vain, when other means fail. Since 1893 I have recommended it in thousands of cases, and owe to it many a gratifying success. In fact, I think it may be classed among the most potent therapeutic agents of all.

Technique.—The bath, as a full-bath, should cover the body to the jugular fossa. The temperature should be 107 to 108°. The patient enters it slowly, so that one or two minutes elapse until he is fully immersed, for many experience pain from even this temperature and become timid. The bather should lie down comfortably on his back, but should not wash himself or make any unnecessary movements, for thus the water will be made less hot to the feel. He is to stay in the bath as long as it is agreeable to him, but the moment his temples pulse disagreeably, or a feeling of apprehension makes itself manifest, he must leave it. Under no circumstances must he remain in the first bath longer than eight minutes, even if he feels well. There should be no cooling by means of a douche, cold sponging, or addition of cold water unless in the eventuality of an attack of faintness. The arising also should be slow, and the drying off process is best done in a sitting posture, precautions which both tend to prevent swooning.

By a strict observance of these rules I have never had to record an untoward accident, and even special precautions for the head, such as a cold compress or a preliminary washing of the head with hot water, are, as a rule, unnecessary, but may be adopted if the bath is to be of longer duration. With babies and children I let the bath begin at 102-106°, filling the tub about three-quarters full. After a minute the child will have become reconciled to the heat, so that the temperature may be raised to 107° or 108° by adding hot water without exciting any particular protest on the part of the little one. At this temperature it is to remain in the bath four or five minutes longer without being rubbed. Then, undried, it is loosely wrapped in a dry sheet and taken to bed to perspire from one to three hours. Most of the children fall asleep at once. Adults who bathe at home may also thus undergo perspiration without being dried. The number of baths should be one or two per day, in special cases even four to six. If the patient stands the bath well the temperature may be raised to 113°, or the time protracted a few minutes; still I have never had occasion to give more than 108° or to extend the time beyond ten minutes, and I regard a more radical procedure as unnecessary in general, at least as being required only in very special cases.

Physiology.—In the act of entering the tub, incident to the intense irritation of the cutaneous nerves, a contraction of the vessels and muscles of the skin causes paleness and cutis anserina. Both will be relieved in a very short while by dilatation of the superficial vessels, so that after the bath the skin appears more or less scarlet. This dilatation is a passive one, the result of a temporary paresis of the constrictors, and therefore to be distinguished from the reactive dilatation of cold irritation. For this reason a cooling process after the hot bath, such as after a neutral or warm one, is nonsensical.

For the same reason no cold can be contracted for some time afterward, for the origin of a cold we assume to be a contraction of the vessels of the skin with an enforced return of the blood to the inner organs; therefore the baths may be taken outside of the home, even in stormy weather, so long as the patient returns, within the next quarter or half an hour, to a shelter where he no longer can catch cold. This constitutes an enormous distinction between, and advantage over, other heat-inducing baths. The arteries are dilated. The sphygmogram is rather dicrotic and the percussion wave is missing. The hyperæmia of the skin means anæmia of the internal parts. This is proved by the suppression of hemorrhage, by Schueller's[3] known experiments on the brain, and by the distinct contraction of the radialis seen by Oliver. Further, Leared, Wordsworth, and Allport[4] have noted a decided and marked paleness of the optic nerve and a diminution in the size of the retinal vessels after a Turkish bath, and have assumed from these phenomena that there is a reduction of the circulation in the brain. I think there can be no reason why this should not be the case in the hot bath. In cases of venous stagnation in internal

organs, the stagnation is temporarily removed, and a more rapid circulation is made possible, which may restore tissues that are not too deeply affected —as, for instance, is evidenced by the immediate success experienced in the case of catarrhal lesions of the upper-air passages.

The changes in the composition of the blood, so much discussed in late years, have not proved essential, and are merely changes in the blood distribution. Only the number of the leucocytes is increased, a state that is sometimes said to be demonstrable even after the elapse of twenty-four hours.[9] The diminution of red corpuscles in the greater arteries is to be explained by their gathering in the dilated small and smallest vessels and, perhaps, by stagnation in inner organs, *e.g.* the liver. An inspissation of the blood occurs only in the minutest degree, even when the bath is radical in temperature and duration, because serum flows back from the tissues into the vessels. Then the muscles are poorer in water and the blood serum is of a higher specific gravity.[10] With short exposures the density of the serum remains stationary, and this may be said to apply to the hot bath. However, these phenomena observed by earlier investigators are entirely refused recognition by Krebs and Martin.[11]

The heart's action is accelerated and the pulse rises rapidly to 100, 120, and over. It is full and large but smooth. When the duration is short the bath acts as a stimulant to the heart, but may, when protracted, lead to heart failure.

If certain authors advise that these baths be extended over a period of 20, and even 60, minutes, I can explain this only on the basis that the water must have cooled very rapidly. My tub, for instance, will lose in 10 minutes 3; in 15, 4, and in 25 minutes, 7 degrees. In my opinion very few minutes will accomplish the desired purpose. The acceleration of the pulse will continue after the bath for about three hours before the normal rate is regained. In cases of retardation of the pulse on account of autotoxic influences this acceleration may restore a normal rate. The respiration is quickened and deepened, the change of gas augmented.

The diuresis is markedly reduced, the urine is more acid, the sweat production enormously enhanced. According to Ries, and contrary to the commonly accepted view, sweat is secreted also during the bath and afterward pours out profusely, especially when the patient is wrapped in blankets. Comparative experiments by Hess, Zelenetsky,[12] and others showed that the quantity of sweat secreted is far more abundant after this application than after any other procedure. The temperature of the body rises quickly, more rapidly than in any other form of bath. With a bath temperature of 107°-108° and a duration of eight minutes, a rectal rise of two degrees and more is observed, and this is achieved mainly through the circulation, a little by direct conduction, and somewhat by increased production.

During the first moments of the hot bath many experience a sense of pain rather than one of heat, but a sensation of utmost comfort will soon set in. The entire nervous system undergoes a local and general temporary stimulation, which also invigorates the protoplasmic activity of every cell of the organism.

According to Maggiora and Vinaj,[13] the amount of work capable of being done by a muscle is reduced after baths of 104°, but heightened after douches of 106°. Baths of 107°, especially when short, may act like the douche. However, the data of the 104° bath are not in accordance with the experience of Bælz and Determann, who, regarding hot baths as a reliable means of invigoration, recommend them without reserve as a restorative when fatigued. My experience confirms that. Certain persons, unaccustomed to the hot bath, feel some weakness or exhaustion after the first or second bath, but there is later on always a marked stimulating effect upon mind and body.

As Winternitz, Jr.,[14] established the CO_2-excretion and O_2-absorption are positively augmented, the decomposition of non-albuminoids markedly increased. After a long dispute the fact has been settled beyond question that the nitrogen metabolism is raised by a hot bath and the destruction is more speedy than even in fever.

However, in my opinion, the influence of the hot bath of 107° to 108° and 8 minutes' duration, as recommended here, is certainly not very potent and, therefore, I do not rely upon it as a means of reducing obesity, as advocated by others. On the contrary, many observers have seen the bather gain in weight after a number of baths.

An absorption of drugs added to the water takes place exclusively with keratolytic substances.[15] Generally the action of the hot bath, which by the way is still far from being absolutely clear, resembles that of steam, hot air, and electric-light baths, but it has this advantage over all these that the rise of temperature and quantity of perspiration is much more marked, and the hot bath should be preferred also when the nervous system is to be spared.

There is no doubt that the success of quite a number of thermal springs and baths with artificial additions, as tan, salts, etc., must be attributed to the high temperature, and I think Baelz's note very appropriate in which he says that, if all these baths were given as a technically proper hot bath, there would be still better results than now.

It is often observed that during longer treatments the pulse by degrees becomes less frequent and the quantity of sweat less abundant. That would argue in favor of an accommodation of the organism, which, in view of the Japanese custom, I do not regard improbable.

Here would be the place to mention the statement of Foss[16] that the unlooked-for incidents of a too far protracted bath with reference to the heart, brain, and respiration can be avoided and removed by the inhalation of pure oxygen, and in this way the bath, if deemed beneficial, may be prolonged at will, especially if the precautions for the head above mentioned are observed.

Therefore the action of the hot bath may be said to be based upon: (1) a powerful stimulation of the entire nerve system for a brief period; (2) an intense revulsion of circulation leading to hyperemisize the skin and unburden inner organs; (3) a perspiration more abundant than after any other form of bath; (4) a raising of metabolism, and (5) the creation of a sometimes valuable leucocytosis. Accordingly, the hot bath is indicated:

(*a*) Whenever we intend to incite energetically the metabolism during a given moment, or, in other words, when we wish to create a "curative fever." For, as Virchow once said, "it may be that a fever has salutary effects, that a fault existing in the organism may be consumed by the grand metabolism of fever." or, to cite Liebermeister, in Leyden's *Zeitschrift für physicalische und diätetische Therapie:* "We may assume that obnoxious organic substances, poisoning the organism, are oxydized and turned into non-perilous combinations, the more so, the more active is the metabolism, the oxidation in the body." Besides, according to Emmerich and Trubois, the activity of Buechner's alexins is said to be enhanced.

(*b*) The hot bath will be indicated where there are toxic substances to be eliminated, either chemicals, as mercury, arsenic, potassium, iodide, etc., or autotoxins. The greater toxic coefficient of sweat produced by physical over that produced by chemical means has been repeatedly demonstrated in medical literature, and it was Brunner[23] who elucidated that even bacteria, such as Staphylococcus albus and aureus, the anthrax germ, and B. prodigiosus are eliminated by way of the perspiration. In consequence of this, Kabierske went so far as to speak of a disinfection of the human body.

(*c*) A third indication exists when we wish to remove exudations and stagnations in internal organs.

(*d*) And fourthly, we may resort to the hot bath, when an energetic incitation of the entire vital cell activity is the purpose, for, to cite Bosanyi, "the mobility of protoplasm is enhanced, and the activity of the vessels and the amount of labor produced by the nerve system are multiplied."

Coming now to special indications, the hot bath is the sovereign weapon, as all writers on this subject agree, against the acute maladies of the upper-air passages. Three baths, given at intervals of twelve hours, will cure the rhinitis of the new-born, often so unpleasant, and that of the adult. The results in cases of laryngitis, tracheitis, bronchitis, and bronchopneumonia are equally excellent, according to Rix, Lasègue, Baelz, Baruch, Matthes, Kellogg, and others. At the Berlin Balneological Congress, Putzer[10] praised it highly for the laryngeal stenosis of measles.

Juergensen[12] and others use baths of only 104°, but of longer duration. According to my experience, the hot bath, as defined above, is more effective and less exacting upon the nervous system. In pseudocroup no other means secures prompter results in my estimation. Further, asthmatic attacks of various origin yield readily, but, of course, when they are of cardiac origin, care must be taken. Emphysema and dry pleurisy should also be mentioned here.

As many believe hay-fever to rest upon a gouty or nervous basis, a trial of the hot bath with this disease and nasal hydrorrhœa is certainly advisable.

Heart disturbances, when the organ itself is not defective, afford no contraindication in view of the short duration of the application, nor do compensated heart troubles or, according to Rosenthal[20] and others, valvular diseases and even angina pectoris. In asthma cardiale I have seen the hot bath act excellently in a case of mitral insufficiency, and other observers record similar cases. Still I wish to emphasize that the physician himself should watch the first bath, and also that he should be thoroughly conversant with hydrotherapeutics.

In kidney troubles, warm and hot baths have long been in use. It is not always easy to decide when cooler, or even cold, warm or heat-producing procedures are indicated, but whenever the last mentioned are deemed the best, hot baths should have the preference, because they are productive of more perspiration and are less exacting in their influence on the heart. It is repeatedly and explicitly stated in the literature that patients prefer this form of bath to any other. Whenever the nature of the case in question will permit it, dropsy and albuminuria often vanish with unexpected rapidity. Even uræmic symptoms hardly form a contraindication, especially when the loss of water is carefully compensated by copious drinks. I wish to emphasize, however, that in all these cases the technique as given above must be strictly followed. When, for example, Liebermeister quickly raises the temperature from 100° to 106° and leaves the patient in the tub up to thirty minutes, I would not regard this procedure as commending itself to imitation; at least such a policy would be adapted only to certain very special cases. In any event it would be more rational to give more and shorter baths.

The results are furthermore excellent in rheumatic diseases of all forms, especially those of a chronic nature. I have often seen workingmen, who every year were unable to work during periods extending over several weeks, restored by the regular use of these baths and now are able to work continuously. Kellogg and Moritz[11] apply two to three baths daily in acute rheumatism in combination with salicylic preparations, and state that thus the doses of the drug can be considerably diminished. Baelz and others recommend baths also in gout, and I believe that a hot bath in all cases of rheumatic or gouty ailments should be tried in the first instance. In the majority of cases the results are satisfactory sometimes not in subacute ones, however, until after a transient exacerbation.

Contrary to Baelz's opinion, Rosin praised the bath in chlorosis in a paper, read at the Sixteenth Congress for Inner Medicine, and I also have seen that often when medicaments failed the baths were successful.

Schmidt[18] observed favorable effects in osteomalacia after hot-air baths, and attributed this to the action on the periosteum and marrow, and, possibly, to an augmented excretion of acids. I would prefer the hot bath in this case. In scrofulosis and rachitis I have used it for years, at weekly intervals or oftener, for the purpose of revulsion and stimulation.

Female diseases comprise an important chapter. Gottschalk[6] extols the hot bath in climacteric troubles and after ovariotomy when the women are suffering from flushes, etc. The effect is, he says, due to lowering of the arterial pressure. If that is true, I wonder why he adds, as he does, Stassfurt salt, and the duration advised by him also seems to me too long. Engelmann,[17] Duehrssen, and others advise warm baths with additions of various salts in chronic, feverless affections of the pelvic organs. Very often, I am sure, a hot bath would be more rational. Almost brilliant results are shown with the host of menstrual grievances. If dysmenorrhœic pains do not stop in all cases, at least they will be alleviated. Profuse hemorrhages, even occurring with myomata, are lessened, and the period is abbreviated.

In the treatment of syphilis the hot bath can properly replace other sweat-producing baths. I have always had satisfaction when using this treatment for inveterate cases of psoriasis, exhibiting large indurated areas. Gokielow[24] recommends it in acute and even moist eczemata caused by local irritants, and in such cases it is said to be astonishingly effective. I do not doubt that in many old and hitherto obstinate skin diseases the hot bath would yield almost unhoped-for results. Rosenthal lauds it in stubborn cases of chancroid. As a rule, torpid ulcers will change their character as they do when local hot applications are resorted to.

To encroach upon the ophthalmological realm, Koch[7] wrote on the hot-air-box treatment for affection of the lids, conjunctiva, sclera, retina, and choroid based on defective metabolism and of gouty, rheumatic, and specific origin. Hot baths may also be given here, instead of the above mentioned treatment, as I have experienced in my own practice; of my cases I will mention only scrofulous corneal affections, and some cases of severe iritis that could not be controlled by the previous

treatment of a well-known specialist and had relapsed again and again.

Another field for the hot bath is in cases of neuritis and neuralgia, which hitherto have been combated with other forms of sweat production. When there is no anatomical lesion present, especially when the case is of rheumatic origin, satisfaction seems inevitable.

In maladies of the central nervous system hot baths are regarded as strictly contraindicated. Most authors, including Baelz, warn explicitly against them. Sometimes lack of success and even damage may be attributed to a defective technique, the bath not being hot enough or too protracted. That good results may be obtained, however, the publications of Schuster,[22] Bouchard, and other French neurologists demonstrate. They report satisfactory results in cases of myelitis lumbodorsalis, hemiplegia, progressive pseudoparalysis, etc. Schuster found that patients not only bore the baths splendidly, but that it proved effective, and he commends them strongly, whenever other methods of treatment prove useless, but, it must always be remembered, strictly as outlined above. Only once, in a tiresome case of locomotor ataxia, I advised the hot bath hestitatingly against the painful neuralgias of the legs, with the result that I had trouble afterward to stop the treatment, for the patient began to regard them as a panacea for all his numerous ailments.

Then again, in the daily routine of practice, there are disorders and rather harmless indispositions, local and general in nature, which, as a rule, are not to be classified either as to diagnosis or as to etiology. Colds, over-exertion, perhaps also autotoxæmia or local defects in circulation, may play their rôle, but no fixed pathological basis can be made out. All these ailments are relieved by a hot bath, which certainly, according to the above outlined indications, is more rational than the multitude of drugs which are picked out often merely by chance, *ut aliquid fiat*.

Finally, the hot bath has been applied in a number of acute infectious diseases with partly unexpected results. Lanaras and Rumpf combated by it the algid and asphyctic stages of Asiatic cholera. Others did not obtain satisfactory results, perhaps on account of defective technique. For a temperature of 108° to 113° and a duration of fifteen minutes are a little too much. Kellogg and others praise it in cases of typhus and similar infections, without regard to the temperature, whenever the circulation is dormant, the nervous system deeply depressed, and the skin cool and inactive. Under the same conditions, in cases of scarlatina, v. Juergensen commends baths at a temperature of 104° and with a duration up to 60 minutes. I do not agree with this advice and insist upon the technique mentioned. The shorter and hotter the bath the more accentuated the stimulation will be. Also in puerperal eclampsia, as Kellogg cites, it proves very satisfactory, and so has it, in my experience, in the stage of collapse in babies with cholera infantum.

Aufrecht, Woroschilsky, Wollisch, and Ewnin report altogether 15 cases of well-defined cerebrospinal meningitis in which the result was brilliant. In all cases of this pyretic affection the temperature fell very decidedly after the bath.

With influenza in the beginning, a bath may be tried. Often its action will cut short the onset, but even if this does not occur, the bath is sovereign in resulting neuralgias and to shorten the term of convalescence.

Finally, hot baths are recommended in infantile convulsions, delirium, and in colics of various origin, and for some time the bath, alternating with cold plunges, has been given to reanimate the asphyctic new-born.

The hot bath is to be avoided positively in marasmus, cases of myocarditis and uncompensated heart troubles, in cases of nervous irritation, with atheroma, when there are fetid masses present in the intestines, in cases of pus collection anywhere in the body, and whenever by inspissation of secretions pus could be retained, *e.g.* in fetid otitis media, epididymitis, and all highly febrile conditions, so long as the factors cited by Kellogg are out of consideration.

All these indications illustrate the range of action of the hot bath. Whoever will handle it properly as to the technique will soon be convinced that it is a most valuable weapon in the physician's armamentarium.

As one speaks of a Brand bath, or of Ziemssen's, the hot bath should be named the "Baelz" bath, in gratitude to him who brought it to us from the far East.

A Sanitarian Duty.—For our own sake, to say nothing of the rest of the world, it is our duty to stamp out yellow fever on the isthmus. That we can do it is proven by what we have done in Havana and Santiago. The isthmus is a much greater proposition, yet we doubt not that American sanitarians will yet accomplish on the Isthmus of Panama, at least so far as the canal belt is concerned, exactly what has been done in Havana and Santiago—reduce the danger from yellow fever to a minimum.—*Montgomery (Ala.) Advertiser.*

THE ORDINARY "X" AND ULTRAVIOLET RAYS IN THE TREATMENT OF TUBERCULOSIS.*

By J. B. RANSOM, M.D.,
PHYSICIAN TO CLINTON PRISON, DANNEMORA, N. Y.

ALTHOUGH so short a time has elapsed since the Röntgen or *x*-ray began to be used as a therapeutic measure, it is fast coming to the fore among therapeutic questions. On every hand there are evidences of increasing interest in this subject, and many of the very best men of our time are devoting their energies to its study and development.

A vast amount of experimentation is going on, and careful observation and painstaking work are giving absolutely positive results in the cure of heretofore if not absolutely incurable, certainly very stubborn, lesions. Notwithstanding this, however, the subject is still an open one. Comparatively little is known as to just how wide a field of application it may have, nor is it yet possible to fix its status in the treatment of disease. The use of this agency is in its infancy, and is restricted largely to the specialist, and is not, I believe, in any large sense, used by the general practitioner.

Like many another great physical force, the use of the "*x*" and light rays in the treatment of disease is, as a whole, little understood. We are all apt to look upon these great forces of nature—because we cannot see with the naked eye their operations and powers—with skeptical indifference; in other words, we do not believe what we cannot see. Because these forces are so much our every-day companions and constitute so entirely our environment from childhood to old age, we overlook their true significance, and their tremendous potency, even in the mechanical and commercial world. We breathe the air, drink the water, feel the warmth, see the light, and use for many purposes electricity, and even see an electric wave shot across 3,000 miles of ocean unchanged, by the Marconi transmitter, but yet, we do not look upon them as presenting therapeutic possibilities.

It is true that, for centuries, more or less has been known of the beneficial and curative effects of these elements. We know that hydropathy has for a long time formed a system of medicine; electricity has been extensively used; the administration of oxygen, heated air, and light have all, to some degree, been developed, and have produced a measure of results. It remained, however, for the discovery of the *x*-ray and radioactive bodies to open our eyes more fully to the great possibilities and almost limitless field of exploration beyond our ordinary vision. If we concede that there is no such thing as solid or stable matter, we then realize that all substance is in motion, and capable, by increased motion, of changing form and shape, and, by a species of harmony in motion, of producing marvelous changes in form and effect.

More especially is this true of the phenomena of light. Vision begins at about 450 billions of vibrations per second, and ceases at 700 billions. In this we catch a glimpse of the stupendous variations of light. At the juncture of 700 billions of vibrations, human vision ceases, and the violet ray begins. Beyond this, these vibrations can only be interpreted by the photographic plate, or the fluorescent screen, when illuminated by the *x*-ray. Thus it is that the *x*-ray, by its penetrating power, lengthens vision, and admits us to a realm of observation heretofore absolutely impenetrable. These *x*-rays are the highest form of vibration we know. So high is their frequency, that they have never been counted. They travel in straight lines, and cannot be diverted by any magnet or means known to us, and they are too small to be reflected by any polished surface we are at present able to obtain.

After the *x*-ray comes the ultraviolet ray, which is a so-called chemical actinic ray with vibrations of two trillions per second. These ultraviolet rays should not be confounded with the blue glass rays introduced by General Pleasanton in the '70's. Finsen of Copenhagen began developing phototherapy by the use of the ultraviolet ray some time in the '90's. They were first developed by sunlight, by means of colored glasses, or prisms, and then later by means of electric arc lamps.

It is well to understand here, that treatment by the *x*-ray tubes is not treatment by electricity, as ordinarily understood. We only use the electric current to develop a higher frequency of light oscillations than can be produced through any other agency. The effect produced upon the tissues is simply a bombardment by light rays producing interchemical action.

In my practice I have used the double-focus, high vacuum tube and the ultraviolet Mount-Bleyer tube. I am now using chiefly this ultraviolet tube, which is a new method of developing the ultraviolet rays by means of electricity. This tube is an ordinary Crookes' tube, from which the gases have been exhausted in a certain way, and the metal disks so arranged that an ultraviolet, instead of a green-yellow ray, is produced. The advantage of this ray over that possessed by the Finsen lamp ray is its greater penetrating power, simplicity, and ease of operation. It does not differ materially from the ordinary *x*-ray tube in appearance and is very easily operated.

The chief use of the *x*-ray as a therapeutic measure, as you are aware, has been in the treatment of malignant growths, such as sarcoma, carcinoma, epithelioma, rodent ulcer and various forms of skin diseases, and, more recently, tuberculous lesions. To this form I shall confine my remarks to-day. Finsen has reported a very large number of cases of lupus treated by the Finsen ultraviolet light, which I omit from this report, as they were not treated by the *x*-ray proper. My own work in this line, as before mentioned, has been almost entirely restricted to tuberculous lesions. I have treated in all forty cases.

The tubes used in this treatment were excited by the current taken from an alternating lighting line, passed through a high potential and a high frequency coil, producing a 7½-inch spark. Exposures are made at a distance of from 10 to 30 inches from the tubes, parts not necessary to expose being protected by sheet lead. Exposures are made about three times a week, or every other day; the length of exposure being entirely governed by the case, and ranging from one minute to ten minutes. By making short exposures, no burns have occurred. Of the forty cases treated, eight, or 20 per cent., were cured, thirty, or 75 per cent., improved, and two, or 5 per cent., discontinued.

CASE I.—A case of tuberculous abscess of apex of right lung pointing above clavicle in triangle of neck. This abscess was incised, and drained, and treated some five months without much amelioration of discharge, or improvement of health of patient. Treatment by *x*-ray began in December last, and immediately there was improvement; the discharge lessened, the sinuses gradually healed, general health was improved, patient was discharged as cured, and has remained well to present date.

CASE II.—A case of tuberculous excavating ulcer

*Read at the annual meeting of the Medical Association of Northern New York, at Saranac Lake, N. Y., 1903.

of ear and face. Treated several weeks by ordinary surgical procedure, but to no avail. Disease made rapid progress until it was submitted to the *x*-ray treatment, when a few exposures resulted in arresting the disease, healing began, and practical cure resulted within a few weeks. The action of the ray in this case approached the marvelous, and patient remained perfectly well up to the time of his discharge, which was ten months after treatment.

CASE III.—One of tuberculous caries of sternum with discharging sinuses. Patient was operated on, and afterward submitted to *x*-ray. He immediately showed improvement, and was discharged from hospital cured.

CASE IV.—Case of tuberculous caries of sternum. Cured by exposure to *x*-ray, and has suffered no relapse up to the present time.

CASE V.—Tuberculous caries of sternum. Treated by incision, drainage, and *x*-ray; improved rapidly under treatment, which was discontinued on account of patient's being discharged and passing from observation.

CASE VI.—Case of tuberculous caries of sternum; treated by incision, drainage, and exposure to *x*-ray; still under treatment and improving rapidly, the carietic process apparently arrested.

My experience with tuberculous diseases of the sternum had up to the time of using the *x*-ray been unsatisfactory, radical operations often failing in eradicating the disease. One case in particular, in which two or three extensive operations had been done, removing a large portion of sternum, did not result in checking progress of disease, and the patient finally succumbed after months of suffering. Thus far, every case of sternal caries has yielded to the *x*-ray, and in it we seem to have a powerful agent in arresting this troublesome manifestation of tuberculous disease.

CASE VIII.—Case of tuberculous caries of metatarsal bones of great toe. Exposure to *x*-ray resulted in rapid healing of sinuses. Case still under treatment with only a few drops of seropus in evidence.

CASE IX.—Case of tuberculous caries of submaxillary. Still under treatment, practically well.

CASE X.—Case of extensive tuberculous caries of foot, leg, and arm. This was a case of long standing sent me by another physician, he having practically despaired of cure, and, I believe, had advised amputation. Nearly all the tarsal bones were involved, and the lower end of tibia. The foot was very much tumefied and twice the normal size. There were a number of deep-seated sinuses discharging fetid pus. Ordinary treatment was persevered in for a long time, with but slight amelioration. Exposure to *x*-ray resulted in immediate lessening of discharge, and final healing of all sinuses, subsidence of tumefaction, and cure of disease, patient having remained well for over seven months to present time. This patient also suffered from tuberculous synovitis of left elbow-joint, in conjunction with caries of head of radius. Drainage, treatment by *x*-ray, which resulted in prompt healing of sinuses with excellent results.

CASE XI.—One of extensive burrowing sinuses in gluteal region, from tuberculous fistula in ano of twenty years' standing. One of these sinuses measured ten inches in length. Treated by incision, curettement, exposure to *x*-ray, under which rapid absorption of infiltrated tissues took place, healing of all sinuses—a most excellent result.

CASE XII.—Case of tuberculous disease of scrotum involving right and left testicles. Treatment—incision of right scrotum, and removal of large tuberculous mass from right testicle—drainage, exposure to *x*-ray. Result, practical healing of right side and lessening of two-thirds of tumefaction of left side. Patient still under treatment.

CASE XIII.—A case of tuberculous synovitis of elbow-joint; still under treatment—improving.

CASE XIV.—One case of tuberculous tumor of abdomen, treated by exposure to *x*-ray. Result—total disappearance of tumor.

CASE XV–XXII.—Eight cases of tumefied axillary and cervical glands. Most of these cases were in aggravated forms, some of the glands showing excessive enlargement. Many of them were of long standing, having resisted all the ordinary means. In several of these cases the glandular enlargements have disappeared, all have improved, and curative results will probably follow in nearly all cases.

In this connection I desire to mention two cases reported to me by Dr. Wm. J. Morton of New York, whom I quote as follows: "It is certain that this class of cases do excellently well under the *x*-ray. I have cured two such cases, each of which having been submitted to five different operations before they went under the *x*-ray, but in each case extensive recurrence occurred. The *x*-ray was the only thing that put an end to the disease." I believe by judicious incision, and persistent use of the *x*-ray, that only in exceptional cases will removal of enlarged glands, or lymph nodes, be found necessary, an operation which an extended experience with this class of cases has taught me is seldom satisfactory.

CASE XXIII.—One case of tuberculous consolidation of lung along track of gun-shot wound; still under treatment, the consolidation disappearing and patient improving rapidly.

CASE XXIV.—One case of tuberculous pleurisy with intercostal neuralgia, very much relieved and discharged from hospital.

CASES XXV–XXXI.—Seven cases of chronic pulmonary tuberculous phthisis, with very profuse expectoration. These cases were treated with marked improvement in quantity and quality of expectoration, general improvement of symptoms. Still under treatment.

CASES XXXII–XXXIII.—Two cases of advanced chronic pulmonary tuberculosis. Treatment was discontinued on account of low state of patients.

CASES XXXIV–XXXIX.—Six cases of chronic pulmonary tuberculosis still under treatment, all doing well.

CASE XL.—One case of tuberculous disease of thyroid gland, still under treatment, improving.

Through my experience of its use, I am satisfied that the *x*-ray, and especially the ultraviolet ray, is a potent agent in the treatment of all superficial tuberculous lesions, and that we have in this ray, a powerful factor in the cure of this class of cases. As to the deep-seated pulmonary lesions, the number of cases treated is too small, and the time elapsing since commencement of treatment too short, to estimate fully what results we may expect from its use, in these manifestations of tuberculous disease. So far as I have gone in its use, I am impressed with its efficacy in this class of cases. It certainly relieves pain, promotes sleep, stimulates local circulation, thus clearing consolidations, and, after a time materially lessens expectoration. There seems no reason why the *x*-ray should not be effective in the treatment of the deep-seated pulmonary lesions. To satisfy myself as to the penetrating power of the rays, I exposed a patient having an ordinarily thick chest to the *x*-ray anteriorly, strapping to his back underneath the scapulæ, two keys, and then holding a dry photographic plate posterior to the keys, and giving the plate an exposure under the high vacuum

tube of sixty seconds. The result of this exposure shows that a very large percentage of the rays pass through the intervening chest walls, the pulmonary structures, and emerge at the posterior wall in a sufficient number to make a fairly clear impression upon the photographic plate.

I know of no other therapeutic agency at our disposal which is able to reach the deep-seated pulmonary lesions so frequently found in pulmonary tuberculosis, and I urge upon you the use of this agency in the treatment of this class of cases. Let me caution you, however, as to its use in recent hemorrhagic cases, as, in my own experience, I had three slight hemorrhages immediately following exposure in cases in which hemorrhages had been of recent origin.

If you ask me how the *x*-ray produces its results in the cure of tuberculous conditions, I shall have to answer, that its precise manner of action is not known. It is believed by many to be due to the development of nascent oxygen in the tissues, or ozone, and their effect in setting up interchemical action. Others believe in the ionization of cells. It is quite positively determined that its action is first destructive, and then reconstructive. That it produces certain marked changes in the cells has been positively proven by microscopical study. The power to inhibit bacterial life is not fully proven of the high vacuum tube. It undoubtedly does this to some extent. The ultraviolet ray, however, is positively inhibitive to bacterial life and growth. This I have already proven to my entire satisfaction in my own laboratory, in which active cultures of tubercle bacilli were exposed for different lengths of time, varying from one minute to thirty minutes, to the ultraviolet ray as produced by the Mount-Bleyer tube. The result was the inhibition of all bacterial life in these tubes, the control culture growing rapidly. This corresponds with the experience of others who have made similar tests.

Here, indeed, is a wide field of research and close observation, and it is to be hoped that every practitioner of medicine will make this phase of therapeutics a subject for thought and experimentation. If the finsen light and *x*-ray apparatus are not available to all, the sun in the heavens certainly is, and light, as a medicinal agent, is at the disposal of every practitioner.

ANTISTREPTOCOCCUS SERUM IN PERNICIOUS ANÆMIA.*

By JAMES J. WALSH M.D., Ph.D.,
NEW YORK.

INSTRUCTOR IN GENERAL MEDICINE AT THE NEW YORK POLYCLINIC HOSPITAL AND SCHOOL FOR GRADUATES IN MEDICINE, ETC.

It is nearly half a century since the distinguished English physician and acute clinical observer, Dr. Addison, described the first cases of idiopathic anæmia, as he called it. Notwithstanding the fact that since then the affection has attracted almost more than its due share of attention, we are as yet absolutely in the dark as regards its cause. It is true we have limited the range of the disease somewhat by the demonstration that cancer, and especially carcinoma ventriculi, may give almost exactly the same clinical picture as pernicious anæmia, and that undoubtedly some of the cases described before 1880 as pernicious anæmia, were really gastric cancer. We have learned, besides, to recognize that severe secondary anæmias due to any persistently active cause, may give the exact clinical picture of pernicious anæmia. Frequent hemorrhages, if repeated, or even the drain upon the system caused by the presence of intestinal parasites such as the anchylostomum duodenale may produce an apparently progressive pernicious anæmia.

Notwithstanding these discoveries as to simulated pernicious anæmia, we are as much in the dark as ever, with regard to the cause of true pernicious anæmia. A group of cases remain in which, without any so far ascertainable cause, a diminution of red blood cells occurs that proves inevitably fatal. The mystery of the etiology of the disease has piqued curiosity and has led to an exhibition of greater and more general interest in the disease than perhaps its comparative infrequency, though this would seem to be less and less a marked feature of the disease, might seem to justify. For pernicious anæmia is certainly commoner than used to be thought, and the fact that one man was able to report over one hundred cases of the disease in his personal experience at a recent meeting of the Association of American Physicians shows that many of the cases are missed in diagnosis.

When, some three years ago, Dr. William Hunter of London offered a new explanation of the etiology of pernicious anæmia and shortly afterward made a suggestion as to treatment founded upon this theory of the etiology, it attracted very naturally a good deal of attention. Dr. Hunter found that in a series of cases of pernicious anæmia, carefully examined for that purpose, practically all of the patients presented an extremely bad set of teeth. He argued that these foci of septic microorganisms supplied a large amount of infectious material that in the stomach gave rise to septic gastritis, as the result of which substances capable of destroying red blood cells were absorbed into the system.

Dr. Hunter described the relationship between the cario-necrosis of the teeth and gastric catarrh, as follows:

"1. There is a limit to the capacity even of the stomach to resist indefinitely for periods of years the continuous presence of pus-forming and other organisms derived from cario-necrotic conditions of the teeth.

"2. Its power of destroying such organisms are never complete in health and are due solely to the presence of free HCL.

"3. These powers become progressively weakened when through any cause an increased and continuous supply of pus organisms is associated with a diminished and continually lessening acidity of the gastric juice.

"4. These two conditions are precisely those produced by chronic cario-necrosis of the teeth.

"5. In time the catarrh of the stomach, so common a sequel of imperfect dentition, possibly of simply an irritant nature to begin with (the result of fermentation), becomes septic in its character and is really due to actual septic infection of the mucosa.

"6. Eventually it may even lead to the deeper seated changes which always result from chronic catarrh, namely, atrophy of secreting structures with increase of fibrous tissue, chronic gastritis with atrophy of the glands."

As Dr. Hunter's theory seemed to explain the association of certain almost constant gastric changes that occur in pernicious anæmia, it seemed all the more plausible. While bad teeth have been looked upon as a frequent source of ill-health because of the mechanical interference with the preparation of food which they presented, the idea of their being a source of infectious material was new. In the moist, warm oral cavity, with plenty of nutrient material, microorganisms might easily grow luxuriously, and immense quantities of them would find their way into the stomach. Dental disease, then, in Dr. Hunter's

*Read before the Section on Medicine of the New York Academy of Medicine.

words, should be set down as a cause of ill-health in consequence of being the continual source of septic poisoning and septic infection, both local and general.

A study of the bacteriology of caries of the teeth showed the character of the microorganisms producing it. The most frequent microorganismal cause was the bacillus gangræna pulpæ which is capable of producing gangrene of the pulp and softening of a tooth even in an alkaline medium. After this specific bacillus the most important mouth microorganisms are the ordinary pus microbes, especially the staphylococcus pyogenes aureus and the streptococcus pyogenes. The streptococcus, above all others, might well be expected to produce serious septic conditions in the stomach, if swallowed in any quantity.

Dr. Hunter found that the treatment of patients suffering from pernicious anæmia with antistreptococcic serum, was followed by beneficial results. Not many cases, it is true, were treated in this way. But three patients made recoveries, two of them in Dr. Hunter's own hands and one in that of Dr. Elder of Leith, which seemed to be due particularly to this new therapeutic suggestion. In one of Dr. Hunter's cases arsenic was also employed. In the other case only the antistreptococcus serum was used, arsenic being deliberately withheld in order to decide as to the efficacy of the serum treatment. Besides this, the mouth was very carefully tended to and antiseptic mouth washes freely employed, in order to prevent further ingestion of septic material from the decaying teeth, besides internal antiseptics to correct the gastric and intestinal septic conditions.

The use of arsenic in pernicious anæmia undoubtedly does good in many cases. Byron Bramwell's suggestion of it is one of the therapeutic triumphs of the last twenty-five years. When that is employed no specific action can be claimed for other remedies. Dr. Hunter himself says that, as the result of the use of arsenic, the character of pernicious anæmia as a disease has changed somewhat since the original description of cases of the disease by Addison, Viermer, and others. Then pernicious anæmia was almost invariably fatal in from six months to a year. Now it is quite usual to have remissions of the disease occur during the administration of arsenic, so that the patients are kept alive for from two to four years.

Dr. Hunter's declaration of the influence of microbes in the digestive tract, has all the more weight as it coincides, or at least is analogous, with certain discoveries of Adami. Adami found that, in cases of cirrhosis of the liver, there were almost constantly present in the liver tissue certain appearances of microorganisms that had apparently found their way into the liver substance from the digestive tract. These bacilli, probably degenerate forms of the colon bacilli, are not thought to be directly related as causes to the hepatic cirrhosis, but are thought to predispose to its occurrence by rendering the liver substance less resistant to irritating agents that find their way into the portal circulation.

Under these circumstances it is not surprising that Hunter's publication attracted considerable attention. The suggestion of a hopeful therapeutic measure for a hitherto hopeless disease was especially interesting. His observations with regard to the occurrence of dental caries in association with pernicious anæmia were not confirmed by other clinicians. In a report on the cases of pernicious anæmia under treatment in Professor Osler's clinic, his assistant said at the last meeting of the American Medical Association that while the mouths of patients had been carefully examined in this regard, no specially bad condition was found to exist in conjunction with pernicious anæmia any more than in any other of the chronic diseases usually treated in hospital wards. Many hospital patients have very bad teeth. Old people especially, no matter what their ailments, are almost sure to have not only defective, but actually carious teeth. Uncleanly mouths and lack of the habit of washing the teeth is almost the rule. This is no more striking among pernicious anæmia patients than others.

Notwithstanding this failure of confirmation, when a pernicious anæmia case came under my observation last summer, I resolved to try the use of streptococcus serum. While there was no doubt about the existence of pernicious anæmia, the blood count showed scarcely 1,000,000 reds and nucleated reds with megaloblasts, the patient, an unmarried woman of thirty-eight, had absolutely no carious teeth, but had, on the contrary, one of the cleanest mouths I have ever seen. She was known to be punctilliously careful of personal cleanliness, so much so that she was considered somewhat of a crank in the matter by her relatives and her teeth were always a special care.

The anæmic condition in this case began after a series of vomiting spells that finally became so persistent that very little food was kept on the stomach. She had always been rather pale, but as the result of malnutrition her pallor increased to such a degree as to make this very noticeable to those who passed her in the street. When I first commenced the use of arsenic in the case, I mentioned the name of the remedy, and was told that one day while walking in the park the patient had heard some one remark on the extreme pallor of her complexion, declaring that it was due to the fact that she took arsenic for the purpose of giving her an interesting pallor. An observation absolutely uncalled for, but that made her hesitate as to the use of arsenic.

After the vomiting had continued at intervals for several months, she had to take to her bed. It was this time that she came under my care. I found nothing in her family history of any interest, her mother was living and well at seventy, and her sister was perfectly well and with no anæmic tendencies. Under the use of arsenic and nux-vomica, she improved considerably for some time. Her appetite became better, and it seemed as though a remission of the disease had begun.

At the beginning of the treatment, when her appetite was very poor, she found grilled bone marrow particularly palatable. There seemed to be a special liability to attacks of diarrhœa in the case, and when these occurred, mutton broth seemed to agree with her better than anything else, and had something of the traditional effect of soothing the intestines that this substance is said by the old people to have.

Notwithstanding the improvement, there were still occasional attacks of vomiting that showed the possibility of a renewal of the progress of the disease In order to get rid of these if possible, Dr. Hunter's suggestion as to the employment of antistreptococcus serum was taken. Six injections of this remedy were given at intervals of about three days At the first injection, about 5 c.c of the serum, as furnished by the New York Board of Health, was employed. In the later injections the whole amount in the vials, as provided by the Board of Health, was administered.

General reaction did not occur. There was only a very slight local reaction after the first dose. After the second dose there was an area about three inches in diameter of urticarial eruption, with redness and itching in the neighborhood of the point of injection.

The remaining four injections all caused a generalized urticaria. This served to make the patient restless and gave a small rise of temperature, but not sufficient to disturb her seriously.

In spite of the injections, the patient did not improve. Vomiting recurred more frequently; and as I left for my vacation in August, the outlook was not very promising. At the beginning of September the patient, after a series of vomiting spells and failure to retain food that had been very trying, succumbed to the disease. The injections of antistreptococcus serum did not seem to have affected the course in the least.

This is not surprising when we consider how many forms of streptococci there are and how, if any, therapeutic effect is to be expected from antistreptococcic serum, it can only be from a serum prepared from the special kind of streptococci that are causing the symptoms. There is no way of determining the special form of streptococcus, and so there is no way of making the remedy suit the special etiological agent in these cases. The history of the use of antistreptococci serum is one of constant disappointment. Its employment in puerperal fever has been absolutely without avail, except in very rare cases. Dr. Hunter's suggestion then would seem to be of no special significance for therapeutic purposes.

HÆMATOMA OF THE STERNOCLEIDOMASTOID MUSCLE; A STUDY OF THREE CASES.

BY THERON WENDELL KILMER, M.D.,
NEW YORK.

ASSOCIATE PROFESSOR OF DISEASES OF CHILDREN, IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; ASSISTANT PHYSICIAN TO THE BABIES HOSPITAL (OUT-PATIENT DEPARTMENT); ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE WEST SIDE GERMAN DISPENSARY.

In the perusal of the literature of the above-named subject, we find that very little space is given it in textbooks. This may be due to the fact that it is considered by some writers to be rather a rare condition, but I am sure that any one having a fair amount of work among children will have seen quite a number of these cases during a year's time.

Hæmatoma of the sternomastoid is invariably caused by injury to that muscle during the birth of the child. In breech presentations in which a midwife tries to disengage the after-coming head by pulling with great force upon the child's legs, this affection is almost certain to follow on account of the laceration of the mastoid muscle. It is therefore more frequently seen in breech than in vertex cases, although any undue traction exerted on the presenting head may also cause a hæmatoma. A partial asphyxia of the infant greatly increases the danger of this injury on account of the atonicity of the muscle and the weakened blood-vessel wall. The hemorrhage takes place into the sheath of the sternocleidomastoid muscle.

In the cases seen by me it has usually been the right side of the neck that has been affected. The expulsive efforts of the uterus alone may be sufficient to cause this condition. The hæmatoma occurs usually at or above the middle of the muscle.

Hæmatomata of the sternomastoid are not usually noticed by the mother or nurse until long after the injury has taken place. The usual history of these cases is as follows: The baby is from two to eight weeks old, and the mother says that "yesterday" or "last night" a lump came in the baby's neck; the mother will positively state that the swelling has not been present for more than a day or two, whereas in reality we know it to be different. The lump was there, but by its gradual hardening it was only recently noticed by the attendant. When the injury occurs, the blood escapes from the torn vessel and causes a soft swelling between the torn muscle fibers; the swelling is somewhat tender. The tumor gradually becomes harder as the clot is converted into fibrous tissue. The skin over the swelling is freely movable and of normal appearance. The size of the tumor varies from that of a small hazelnut to that of a walnut; sometimes the whole length of the muscle is involved.

The characteristic position in which the infant holds his head is noticeable. The head is drawn toward the affected side by the contraction of the muscle. The usual duration of the swelling is from one to three months. A torticollis may persist after the swelling has disappeared.

The differential diagnosis between hæmatomata and swollen lymph nodes is easily made by the fact that the hæmatomata are found situated *in* the substance of the muscle while the swollen glands are not.

Treatment: Most authorities agree that the best form of treatment is to massage gently the tumor

Characteristic position of head in hæmatoma of the sternomastoid muscle.

when soft and tender and then to increase gradually our manipulations as the swelling becomes harder. I believe that all of these tumors will be absorbed if only given time to do so. If in later years of life there remains any vestige of the tumor, surgical means should then be employed and the tumor removed. After a hæmatoma has been entirely absorbed, a torticollis may persist and require correction either by apparatus or tendon division of the muscle.

There are some cases in which the parents will not wait for time to cure this affection, and they wish something done *immediately* for the removal of this hard disfiguring lump in their baby's neck! Such cases—and they are happily few in number—are referred to the surgeon. I have seen some brilliant results attained by the early use of the knife in cases that would *not wait* for time and nature to cure them.

CASE I.—Harry L., seven weeks old. Mother has five children; two dead, one was stillborn, the other died of pneumonia. Mother has had two miscarriages. Family history negative. Normal birth, vertex presentation. Mother says that a midwife "pulled the baby out by the neck." Mother first

noticed the swelling when infant was two weeks old. Infant is well every other way. Mother says lump is gradually getting smaller. This case was seen some months after above history was taken, and the lump had entirely disappeared.

CASE II.—Sarah F., four weeks old. Family history negative. Mother had one other child which died of diarrhœa. No miscarriages. Baby is breast-fed. Labor lasted nineteen hours, head presentation, no instruments used. Baby was thought to have been dead when born, and it took one hour to resuscitate the infant. Baby is brought to the hospital for a swelling on the left side of neck, which has been present since birth. Mother thinks the swelling has been growing larger. Otherwise baby is well. This child was seen one month after above history was taken and swelling has decreased in size.

CASE III.—Frances D., four months old. Easy labor. Four children living. Family history negative. Mother says that the child always had "a choking." The baby had tonsillitis when two weeks old, and the neck was greatly swollen; the swelling soon disappeared. After one week the swelling came back.

Position of tumor in hæmatoma of the sternomastoid muscle.

A small lump can be felt at the right side of the neck, in the middle portion of the sternomastoid muscle. The head is turned markedly toward the affected side. Mother says that the lump is growing larger. Baby cries incessantly. Notwithstanding that the mother was assured that in all probabilities the swelling would disappear of itself if left alone, she persisted it had been growing larger of late, and wanted to have "something done" for it surgically. The child was referred to Dr. Sinclair Tousey, who operated the following day. A swelling was found in the substance of the sternocleidomastoid muscle so intimately connected with the muscle fibers that the muscle was divided, the tumor removed, and the two ends of the muscle were sutured together. The child made an uninterrupted recovery, no torticollis resulted, and the parents are greatly satisfied.

The tumor was sent to Dr. William B. Noyes for a pathological report. The report was as follows: "I have examined several sections of your specimen and am unable to find anything but bundles of striped muscular tissue, fibrous connective tissue and leucocytes sufficiently numerous to indicate inflammation."

From a study of the above three cases it would seem evident that in a case of hæmatoma of the sternocleidomastoid muscle, we have a laceration of, exudation in, and slight inflammation of the muscle itself, and that palliative measures are alone indicated in all cases of this affection in infants.

165 WEST EIGHTY-FIFTH STREET.

Inventor of the Iris Diaphragm.—Microscopists and photographers have long been under an unrecognized obligation to a man who died in England last month. He was the inventor of the iris diaphragm, a convenient attachment to certain optical instruments. The ease with which the size of the central opening in this apparatus can be varied without altering its circular shape makes the diaphragm not only highly useful, but also one of the prettiest bits of mechanism ever devised. John Henry Brown, its author, took out no patent and never reaped any pecuniary reward on the contrivance, but he must have had the satisfaction of knowing that he had rendered a practical service to science.—*The Tribune.*

The Blunt Hook.—Ponfick considers that the ill-repute into which this instrument has fallen is not deserved, and that when properly used it forms a most valuable aid to the obstetrician. The chief source of difficulty in the past has been the improper design of the instruments used. The author's modified instrument is largely the result of improvements by Küstner and differs from the conventional type in the thickness of the hook, which has a diameter of one centimeter; a length of only twenty-eight centimeters, to prevent attempts at its use in improper cases with the breech out of reach; a pelvic curve, and a convenient handle. The chief point of the author's communication is his insistence on the necessity of applying the hook to the posterior thigh. This is always hard to reach and makes the operation a difficult one, but it is this hip that is causing the delay in delivery, and the reports of authors show that when applied to the anterior hip the delivery is always a protracted and difficult one, whereas when the hook is once in place over the posterior hip the remainder of the extraction is very rapid and easy. With the author's instrument the maternal mortality has been o, that of the children also o, with one fracture of the femure in twenty-six cases.—*Monatsschrift für Geburtshülfe und Gynäkologie*, Vol. XVIII, No. 6.

An Insanitary Temple of Hygeia.—We remember in a foreign church coming across a table which was covered to the depth of an inch by a veritable dust drift; on this some sarcastic visitor had written with his finger, *Domine dilexi decorem domus tuae.* Even at home churches do not always illustrate the saying that cleanliness is next to godliness. But one might reasonably expect to find better things in the Temple of Hygeia itself. It is with sorrow, therefore, that we have to record that discoveries made in the buildings in the Rue des Saints-Pères, vacated some time ago by the Paris Academy of Medicine, show that the holy fathers of medical science, while fulminating *urbi et orbi* against transgressions of the sanitary law, had for many years been—we hope unconsciously—providing in their own official dwelling a striking object lesson of the very evils which they were in the habit of solemnly anathematizing in places on which the sacred light of hygiene had never shone. The sanctuary of the Temple—the room in which the Council of the Academy used to hold its meetings—was found to be a kind of museum containing specimens of Paris dirt, collected in the course of many years. When the Academy gave up possession it must, in a literal sense, have shaken the dust of its ancient home off its feet. As a first step in the process of purification the carpet, worn and heavy with the dust of ages, was taken up, when to the wonderment of the beholders, another carpet, still more ragged and grimy, came into view; under this was another, below that again a fourth and so on till some ten layers of moldering carpet had been removed. The work must have resembled the excavations which reveal several ancient cities lying on the top of each other. Imagination shudders at the thought of the myriad tribes of bacilli, streptococci, and other invisible enemies of the human race which so long found an undisturbed shelter within the four walls where the prophets and leaders of medicine were taking counsel how to compass their destruction.—*British Medical Journal.*

PROTOZOA OF SCARLET FEVER.

THE researches of Dr. F. B. Mallory of Harvard University which culminated in the discovery of protozoon-like bodies in the skin of those dead from scarlet fever and which appear in the *Journal of Medical Research*, January, 1904, deserve careful consideration for at least two reasons: (1) Because of the unsettled state of the etiology of this disease; (2) Because Dr. Mallory has presented his results in a fair and unbiased manner, not claiming to have discovered the causative agent of scarlet fever, but pointing out the reasons why it is possible that such may be the case. Regarding the occurrence of these bodies, Dr. Mallory's statements are in brief as follows: They were found in four cases of scarlet fever which died in the eruptive stage. Three of the cases died on the second day, and one on the ninth day of the eruption. In three of these cases the bodies were present in the skin, but in one they were found only in the epidermis of the tongue. In six other cases which died early in the disease no bodies were found. The material available from these, however, was not sufficient for careful study. A number of cases which died in the desquamative stage were examined with negative result. The examination of the skin taken from four patients ill with the disease likewise proved negative. In these cases the examination of blood smears, nasal and lacrymal discharges and swab preparations from the back of the throat showed none of the protozoon-like bodies. In describing these bodies the author divides them into two classes: (1) Bodies which are round, oval, elongated or lobulated, and which are finely or coarsely reticulated. They may contain granules or vacuoles. The finely reticulated bodies are found between the epithelial cells in the lower layers of the epidermis or in the protoplasm of the epithelial cells lying in vacuoles. In the corium these bodies are found close to the epidermis in the most superficial lymph vessels and spaces. The coarsely reticulated bodies are found only within the epithelial cells lying in vacuoles. (2) Radiated bodies. These are usually spherical in shape. They show a round central body around which are grouped on optical section from 10 to 18 narrow segments. They are present in vacuoles in the protoplasm of epithelial cells and free in lymph vessels and spaces of the corium just underneath the epidermis. The majority of these forms suggest the schizogony of the malarial parasites. They are, however, somewhat larger. The first group may be stages in sporogony, or simply due to degeneration of some of the other bodies.

It is evident that the presence of these bodies can be accounted for only by three suppositions: (1) They may be artifacts. (2) They may be cell degenerations. (3) They may be protozoa. Dr. Mallory denies that they are artifacts, for two reasons: (1) Because their number varied in stained sections made from three pieces of skin from the same case, although all the material was fixed and stained in the same jar. Thus they were numerous in the first, few in the second, and entirely absent in the third. (2) Because the bodies were as numerous in sections of the skin stained immediately after the autopsy as in those prepared at the present time, five years later. To our mind these reasons are insufficient. It is a common observation in laboratory work to find that the number of obvious artifacts (precipitates, etc.) varies greatly in sections fixed and preserved in the same jar at the same time. Furthermore, artifacts are as apt to be as numerous in sections from fresh tissue as from such as has been preserved for a long time. By far the best evidence which can be submitted against the artifact origin of these bodies is to be found in the drawings and photographs submitted by the author. In these the morphology of the bodies is so regular that it at once negatives the possibility of their being artifacts. Any one who has had any considerable experience in minute pathology would at once support this view upon looking at the specimens submitted. To suppose that they are artifacts is therefore absurd. Dr. Mallory does not think that they are degeneration products, because they occur not only in and between the epithelial cells of the epidermis, but also free in the superficial lymph vessels and spaces of the corium. Also because they are found in epithelial cells which are in mitosis. Furthermore, because their size, morphology, and staining reactions are different from various degenerated leucocytes and epithelial cells which are present in the skin. The question of confounding cell degeneration products with protozoa is a matter which at the present time is being carefully considered both in this country and abroad. Much work has been done upon the subject, but it is as yet by no means settled. We know, however, that such a confusion is of comparatively frequent occurrence even with experienced workers, and that if the question is ever to be solved, it must be done by means which have not as yet been brought forward. At present, therefore, no one can say with surety whether or not these bodies are degeneration products. From their appearances we are inclined to the belief that they are not, but we believe that they have not been sufficiently observed to say with positiveness that they are not products of degeneration. Granted that they are protozoa, what is their etiological relation to scarlet fever? Dr. Mallory thinks that they have a casual relation to the disease and are not normal or accidental inhabitants of the skin. He regards this as so because they have not already been discovered in all the work which has been done upon the skin in the past twenty-five years, and because in the examination of the skin of fifty-four cases of smallpox made at Harvard during the past year in which the same methods of staining and fixing were employed, no such bodies were found. It is obvious at once that these reasons are not conclusive, and that they only throw a faint glimmer of possibility

toward the etiological relation of these bodies to scarlet fever. We may get some idea of what is necessary to establish this relation by considering the factors which are accepted in proof of the admitted etiological relation of another protozoa to another disease—the malarial parasite to malaria. These factors are as follows: (1) The constant presence of the parasite in the blood of malarial patients and its absence in other diseases. (2) The relation between the development of the parasite (sporulation) and the symptomatology of the disease. (3) The demonstration of the action of the parasite upon the red blood cells. (4) The positive results of inoculation experiments. So far as the present subject is concerned, analogous factors have not been shown. The number of cases examined, together with the negative results, is entirely too small to say with any certainty whether or not these bodies are at any time present in the skin of all cases of scarlet fever. The developmental cycles of the growth of the parasite have not been clearly traced. The relation of its development to the symptomatology of the disease has not been shown. Under these conditions all opinion must be withheld concerning its etiological relation to scarlet fever. However this may be, Dr. Mallory deserves credit for his observations, and especially in making them public at the present time before his proofs are in any way complete. By so doing he has opened the way for extended observation, and it is to be hoped the speedy solution of the question. When work is submitted in such a spirit the author will receive nothing but praise, although his results may ultimately be found not all that they promise.

THE MODE OF TRANSMISSION OF PLAGUE.

In the report of the Board of Health on a second outbreak of plague at Sydney, Australia, Dr. J. Ashburton Thompson gives the results arrived at by himself and his associates from a study of the epidemic of 1902. Elsewhere the maintenance and spread of plague are ascribed to human intercourse (directly with the sick or indirectly through articles infected by them), and to place infection. It had been shown that the epidemic of 1900 in Sydney was not so caused, and the experience of that of 1902 only served to confirm and amplify the former observations. The share played by the rat had been left by observations made elsewhere, a doubtful matter. But in Sydney, in 1900, the conclusion had been arrived at that plague rats constituted the sole source of infection. Though a good deal of evidence in favor of this view had been furnished, it, nevertheless, was incomplete. In all probability, however, the rat cannot unaided disseminate epidemic plague, and an intermediary is necessary to carry the infection from it to man. In 1898 Simond suggested that this intermediary might be a flea or bedbug. Before the epidemic of 1900 Thompson had accepted this hypothesis as explaining a greater number of reported and apparently discordant facts than any other. By the end of the epidemic of 1900 the hypothesis had been accepted by the Department on the ground that it, and it alone, seemed capable of coördinating the observed facts, and at the end of the second epidemic it remained in undiminished favor. In 1900 the Government did not sanction the Board of Health's plan of campaign, and it required isolation of all contacts and as strict a quarantining of infected premises during cleansing as circumstances would permit. During the epidemic of 1902, however, the Board of Health was given a free hand, and it merely removed the sick to hospital where visitation of friends was allowed, but the hospital was rendered rat-proof. The movements of other members of the household were not interfered with. The members were advised to leave their dwellings during the disinfection, but were not compelled to do so. Till after disinfection no outsiders were allowed to enter the premises. Disinfection was always very prompt, and was usually completed within thirty-six hours after the patient's removal; and in case of theaters and hotels it occupied a longer time and included structural repairs necessary to exclude rats. The movement of merchandise from infected areas was not interfered with. In 1900 the cases were 303, the deaths 103; in 1902 the cases were 139, the deaths 39. The mortality in 1900 was thus 34 per cent., while in 1902 it was only 28 per cent. The cost in 1900 was 176,000 pounds sterling; in 1902 only 24,000. These figures are held to justify the Board's radical departure in relation to the mode of dealing with the matter of contagion. Dr. Thompson says: "The promise of safety for the future lies neither with the attempts to prevent the importation of plague rats (which must fail from time to time), nor with attempts to exterminate the rats infesting the locality to be defended (which we have learned is practically impossible), though both of these measures have their valuable uses, but in habitually excluding rats from inhabited premises. This, manifestly, is a defense which can be set up successfully by local authorities; it requires persistent effort, but involves hardly any expenditure of municipal funds."

As regards the epidemic of the 139 cases, 133 were of the bubonic, and 6 of the septicæmic form. The ambulant cases did not exceed 7 or 8. The onset was usually sudden (in 14 cases, however, gradual), with headache, general malaise, sooner or later vomiting, feverishness and shivering, and rather often diarrhœa and colic. Rather frequently attention was directed thus early to the later bubonic gland by a sharp pain, with or without swelling. In 123 cases (with 32 deaths) the bubo was solitary, and in 106 cases it was inguinal. In 6 cases (with 1 death) there was no bubo. More than twice as many men as women were attacked, and in 1900 the proportion was much larger.

Returning to the question of the *modus operandi* of the infection the author narrates chronologically their mental itinerary over the facts—how they found no evidence for place infection in the sense that it has been found in India; how many individual cases seemed to throw doubt on the plague rat theory, as although propinquity of the latter seemed necessary, contact did not, and, moreover, far more commonly only one out of a household of several was attacked; how the ascertained presence of plague rats was not invariably or even commonly attended with plague; and finally how the apparent absence of plague rats did not betoken safety from it. Still a direct and close connection between the presence of plague rats and plague was found rather more often than not, and they learned that

the considerable proportion of failures was, in all probability, merely incidental to the search conditions. By a rejection successively of the possible hypotheses of infection via food infected by plague rats, and that of an accidental infection of open wounds from articles similarly infected (both of which modes seem incompetent to offer a regular and systematic source of infection), the author and his associates were irresistibly led, as a diagnosis by exclusion, to think of some agent which was locomotive and to which the sound skin offered no impenetrable obstacle. Of these the flea seemed best to fulfil the conditions. As soon as this was recognized, it appeared that the hypothesis of the flea, taken in conjunction with recent observations on its habits, was exactly what was required to reconcile the apparent contradictions observed; to explain not merely the erratic incidence of the plague, but also the absence of any great probability of the infection being received by man from plague rats present on inhabited or frequented premises.

The crudity of the criticisms of Nuttall and Galli-Valerio that "rat fleas" will not bite man, is exposed by the observations of Dr. Tidswell, who found that both *Pulex pallidus* and *Pulex fasciatus* did so repeatedly, and by the laboratory experiments made in Sydney, which proved that even granting that the "rat fleas" may prefer to feed on rats, a no more recondite stimulus than hunger is needed to induce them to feed upon man. Furthermore, Raymond and Gauthier have shown that "rat fleas" will bite man, and that they are capable of transmitting the disease from one rat to another, and the latter fact has been confirmed by Dr. J. S. C. Elkington at Bombay. The Sydney observers found four species of fleas on rats, namely, the two above noted, *Pulex serraticeps* and *Typhlopsylla musculi*. Of these the last seemed not to bite man, but all three pulices did. The case then comes down to this: There are two chances at least for man to escape infection, for, first, the fleas from an infected rat may not reach him, and, second, they may do so at a time when they are not urged by hunger to attack an unaccustomed host. These chances amply suffice to account for the frequency with which all the persons inhabiting premises known to harbor plague rats, escape; and also for the rarity with which more than one person is attacked in a household consisting of many, all of whom appear (but only appear) to have been equally exposed to contagion. In conclusion we have, of course, only been able to give the merest outline of this valuable contribution to our epidemiological knowledge.

Note on Scurvy as a Cause of Hæmaturia in Infancy and in Old Age.—R. Shingleton Smith reports two cases of scurvy, one an infant and one in a person aged eighty-seven years. Both patients were fed on sterilized milk and proprietary foods. In both the hæmaturia rapidly subsided in the administration of an antiscorbutic diet. The case of the infant shows that hæmaturia may be almost the only manifestation of scurvy in infancy. The other case suggests that some cases of hæmaturia during adult life may be due to this condition. It would probably be most frequent among chronic invalids on account of their artificial and restricted diet.—*The British Medico-Chirurgical Journal.*

POE AS A DIPSOMANIAC.

EDGAR ALLAN POE was, perhaps, the most conspicuous example of a dipsomaniac ever known. His mind was to some extent unbalanced, and most assuredly, in many respects, he was not as other men are. It is beginning to be generally recognized now that he was not, as was the popular belief, merely a vulgar and vicious drunkard, but, on the whole, was a man more to be pitied than blamed. Many, within the past few years, have taken up the cudgels in the defence of the unfortunate, erratic poet, and have helped to remove some of the stigma which attaches to his name.

In the January number of the *Arena*, Dr. William Lee Howard of Baltimore gives a scientific and technical account of Poe's physical and mental attributes, thereby explaining to his own satisfaction the poet's habits. In the first instance, he quotes the following description of Poe, written by himself in a letter to a friend: "But I am constitutionally sensitive—nervous in an unusual degree. I became insane with long intervals of horrible sanity. During these fits of absolute unconsciousness I drank—God only knows how often or how much. As a matter, of course, my enemies referred the insanity to the drink rather than the drink to the insanity."

Dr. Howard characterizes the foregoing as the first accurate statement we have of the definition of the disease dipsomania, as distinguished from the vicious habit of drunkenness. The writer then goes on to say: "The poet was not a man addicted to the habit of intoxication, but belonged to that class of psychopaths too long blamed and accused of vicious habits that are really the unfortunate symptoms of disease—a disease now recognized by neurologists as a psychic epilepsy, and no more under self-control than is the ordinary epileptic attack."

The victims of such psychic explosions are, according to Dr. Howard, individuals born of unstable nervous organization; unfortunate persons who struggle throughout their lives with all the outward appearances of a well-adjusted physiologic machine, yet who are silent sufferers of intense psychic disturbances. These symptoms of an unbalanced, unequal organization take various objective forms. Such are seen in the startling precociousness of a genius; the meteoric career of a writer who dies before he reaches the age of full manhood in the normal person; the bizarre and morbid paintings of a youth who succumbs ere adolescence has departed, and in the man so poisoned by products of his own body that the higher brain centers are submerged, and the nerve cells, cry, shriek for alcohol as though the fiend of ancestral impulse knew the will was temporarily destroyed, and hence entered to wallow in its riotous delirium. It was to this latter class of unfortunates that Poe belonged, and in his words, poetic prayers, and phantasies the neurologist can see the suffering and recognize the feeling of hopelessness ever present in the unjustly accused. In the opinion of the writer, these dipsomaniac attacks are symptoms of disorganized brain cells. These cells become poisoned at irregular intervals by the bi-products of the physiologic system which are retained in the body through a lack of perfect functioning of the nerve cells—faulty metabolism. These toxic materials are accumulating, and when they have reached a certain potency, overpower the will,

judgment, and self; the real ego is for the time being suppressed, and we have a temporary insanity, its principal symptoms being an imperative, uncontrollable demand for narcotics in any form. Each cell naturally diminishes the resisting power of the brain cells, and augments the basic cause, and the result is an increase of frequency in the attacks until the somatic end.

It is likewise pointed out that in the full development of the mania, the ego is completely suppressed, and the individual disappears from home and friends for weeks and months. There is a cerebral palsy which permits the sufferer to perform various complex and apparently reasoned acts of which he will retain no recollection when he has recovered from the effects of the attack, and which may be quite at variance with his usual behavior.

Dr. Mercier, writing in Allbutt's System of Medicine, agrees in the main with Dr. Lee's views on dipsomania, but lays especial stress on heredity as a strong predisposing factor. He speaks thus of dipsomaniacs: They come of a stock that is of unsound, nervous constitution. Often they are of insane parentage. Often one of the parents has exhibited the same vice in the same form. Often their near relations suffer from other nervous disorders. Quite early in life—at or soon after adolescence—they exhibit the tendency to drink to excess, and the tendency shows a definite periodicity." Dr. Rolleston, also writing in Allbutt's System of Medicine, says: "Dipsomania attacks only those who have a decidedly hereditary taint, or who have acquired a certain irritability of the nervous system from head injuries, sunstroke, and the like." The same writer expresses the decided opinion that dipsomania evidently belongs rather to insanity than to alcoholism.

These views on alcoholism are those which have been long held, but recently a body of men have arisen who deny that heredity has anything whatever to do with the matter. Dr. Archibald Reid is the leader of this band, and his opinions were dealt with editorially at some length in the MEDICAL RECORD of September 19, 1903. It is only reasonable to suppose that the children of drunken parents are cursed, with a neurotic and unstable temperament, and may inherit a certain degree of predisposition to drink. The theory that dipsomania is more closely allied to insanity than to alcoholism is a plausible one, and the actions of persons who possess this habit would seem to show that they are to a great extent irresponsible. The whole question, however, will require much further investigation before dogmatic statements on the subject can be made.

MECHANISM AND TREATMENT OF MIGRAINE.

A recently published monograph by Dr. Francis Hare, Inspector-General of Hospitals, Queensland, contains a very interesting study of the mechanism and treatment of migraine. During the paroxysm a widespread vasocontraction of the cutaneous vessels occurs. This contraction is usually most marked in the extremities, but the face may also be affected. This vasoconstriction is compensated to some extent, if not always fully, by an area of intense vasodilation in some part of the cranium. The presence of this vasodilation cannot always be demonstrated, but at times the retinal vessels may be seen to be dilated and the optic papilla red and œdematous. Some have thought that the vasoconstriction was the cause of the pain in migraine, but it must be evident that such cannot be the case. During the paroxysm the cutaneous vessels of the extremities, as just said, are in a state of vasoconstriction, yet the extremities are never the seat of the pain. On the other hand, in a vasodilation, localized in an area situated anatomically as is the pericranium or dura mater, we have the essentials for the maximum of vascular distension and nerve pressure in the latter area. The pain, therefore, must be actually due to the vasodilation of the vessels of the cranium, although this may arise in the nature of a compensation from a vasoconstriction of vessels elsewhere in the body. If this be true anything that increases the vascular distension of the vessels of the cranium should in migraine increase the pain, and controversely those means which decrease such a distension should relieve the pain. As a matter of fact, it is easy to show that such is the case. The vascular distension in a dilated area may be reduced (1) by pressure on the main arterial trunk, supplying it; (2) by promoting vascular constriction in the small vessels of the part; (3) by promoting vasodilation elsewhere or generally; (4) by reducing the force or frequency of the heart's beat, and (5) by reducing the total amount of blood in the circulation. Controversely the vascular distension in a dilated area may be increased (1) by pressure on arterial trunks supplying collateral areas; (2) by increasing vasodilation in the part; (3) by increasing vasoconstriction elsewhere or generally; (4) by increasing the force or frequency of the heart's beat, and (5) by increasing the total amount of blood in the circulation. Clinical observations and the treatment of migraine in line with these suggestions show that the above theory of the mechanism of the pain is correct. In cases with dilation of the temporal artery of the affected side, pressure on this vessel always affords relief. If the relief is not complete it is certain that this vessel does not control the whole of the dilated area. In unilateral migraine pressure on the corresponding common carotid always gives immediate and complete relief to the pain. In bilateral migraine pressure on either common carotid relieves the pain on the corresponding side, and increases it on the opposite side. In cases of bilateral occipital migraine the compression of both occipital arteries gives immediate relief. In cases of intense pancranial migraine complete cessation of pain follows compression of both temporals and both occipitals. In nearly all cases of migraine compression of the painful area of the scalp affords marked relief. Vasoconstriction of the small vessels of the pericranium may be produced by cold lotions to the head or the ice-cap. In cases of pericranial migraine such applications give complete relief while hot applications always increase the pain. The production of vasodilation in areas other than the seat of pain may be brought about in several ways, such as hot applications to the extremities, dry cupping of the thorax and the administration of drugs like nitrite of amyl and nitroglycerin. Fever, except when associated with rigors, also produces a general vasodilation, and it is a common observation that persons afflicted with migraine never have attacks when suffering with fever. Careful observations have shown that the introduction of the ordinary tape seton relieves migraine, because of the fever which results from the attending suppuration. The application of cold to the body in any form except to the affected area always produces general vasoconstriction, and increases pain in migraine. All drugs which reduce the force and frequency of the heart, decrease or entirely relieve the pain while the controverse holds true. The effect of a reduction of the total amount of blood to disperse migraine is seen

in hemorrhage of all kinds. Many observers have cited instances of this sort. The evidence in favor of the view that the pain of migraine is due to vasodilation of the affected area seems complete. It is highly probable that the other sensory symptoms, among them the initial symptom often spoken of as the migrainous aura, own a similar mechanism.

Mechanism of Treatment of Asthma.

In the monograph alluded to in the foregoing Dr. Hare also considers the mechanism and treatment of asthma. He regards the production of the asthmatic paroxysm as entirely analogous to that of migraine—that is, due to a vasodilation of the blood-vessels of the bronchial mucous membrane which is compensatory to a vasoconstriction of the cutaneous vessels in general. In asthma, however, he concedes that in some instances the bronchial vasodilation may be primary and the general vasoconstriction secondary and compensatory. Nevertheless in either instance these opposite vascular conditions are coexistent and correlative. Thus the dyspnœa of asthma becomes the true analogue of the headache in migraine. The widespread area of vasoconstriction is found to occupy practically the same regions in asthma as in migraine. In both instances there is the same pallor, anæmia, and sense of coldness of the extremities. The pulse during severe asthma is always small, and this smallness is in direct proportion to the intenseness of the dyspnœa. Many of the premonitory or initial symptoms of the asthmatic attack seem to depend upon this general vasoconstriction—as for instance, the polyuria, the drowsiness, and the paræsthesi e of various kinds. That vasodilation occurs in the bronchial area is probable from many observations and on many grounds. In several cases it has been actually seen by the aid of the laryngeal mirror. Moreover, the association of asthma with urticaria, especially urticaria of the mucous membrane of the oral cavity, is a matter of common observation, and it will be admitted by all that urticaria implies vasodilation. The prædyspnœal progressively increasing distension of the chest which occurs in asthma is quite compatible with a progressively increasing swelling of the mucous membrane but less so with the idea of a muscular spasm of the tubes. The pathological lesions of the bronchial mucous membrane recently found by Frankel in a case of asthma ending in death during the paroxysm are quite consistent with the theory of vasodilation. The suddenness of the onset and subsidence of the asthmatic paroxysm is often adduced as an argument in favor of the theory of muscular spasm of the bronchioles; but those who have watched a case of acute urticaria will be apt to realize that the onset and subsidence of vasodilation is amply rapid to account for the phenomena of the most explosive asthmatic paroxysm. Clinical experience also substantiates the theory of vasodilation. Everything which tends to reduce the swelling of the mucous membrane in the involved area will tend to relieve the dyspnœa and controversely. The The swelling may be reduced (1) by increase of the mucous secretion; (2) by vasoconstriction in the affected area; (3) by vasodilation elsewhere or generally, (4) by reduction of the force of the heart's beat, and (5) by reduction of the total amount of blood in the circulation. Controversely the opposites of these measures will increase the swelling of the mucous membrane. The inverse relation between the amount of secretion and the intensity of the dyspnœa may be observed in the purest varieties of "spasmodic asthma." It is a common experience that drugs which promote secretion and expectoration relieve asthmatic dyspnœa and controversely. The happy action of the iodide of potassium in asthma may in part, though not altogether, be explained in this way. The local application of cold to the bronchial mucous membrane and the attendant vasoconstriction brings relief in asthma. Here, of course, cold can be applied to the dilated area only by means of cold air, and it is evident that much of the relief which the asthmatic obtains by sitting at the open window in winter comes about in this way. But the inhalation of certain fumes also produces a vasoconstriction of the vessels of the bronchial mucous membrane. The inhalation of these fumes regularly gives relief in asthma—such as the smoke of stramonium, burning nitre-paper, and the vapor of ammonia. The same result is obtained by the application of chronic acid to the inferior turbinated and the inhalation of chloroform. The production of vasodilation in areas other than the bronchial or generally is an important means of relief in asthma. In this way is to be explained the well-known beneficial results following the internal administration of amyl nitrite, nitroglycerin, stramonium, belladonnæ, alcohol, and opium. Heat is one of the most efficient general vasodilators, and a hot bath rarely fails to give some relief in an asthmatic paroxysm. Hot applications and dry cupping to the chest are also of marked service. Reduction in the force of cardiac action is also followed by relief. In this way the action of ipecac, tartar-emetic, lobelia, and tobacco is to be explained. All drugs which increase cardiac action must be carefully avoided. Finally a sudden reduction in the mass of the blood will tend to reduce arterial pressure and thus reduce the strain upon dilated vascular areas. From this we get the rationale of the immediate beneficial influence of venesection and accidental hemorrhage upon the asthmatic paroxysm. On the theory of vasodilation the action of all of these means is easily explained, but the supposition that bronchial spasm is the cause of the dyspnœa would hardly assist us.

Hospital Ships.

Now that a war between Japan and Russia is actually in progress, and that several sea fights have already taken place, the question of hospital ships is an interesting one. The origin and evolution of the hospital ship is of recent date, the Spanish-American War witnessing the first properly equipped vessels of this character. Hospital ships in the war with Spain amply justified their employment. Again in the Boer war, hospital ships proved themselves of great service. A far more searching test of the value of these vessels will be given in the war now raging between Russia and Japan, for the navies of each country are nearly equal, and the fighting will be much keener than in the Spanish-American War. While the Boer war can hardly be considered as a fair trial of hospital ships, as the fighting was entirely confined to land. The *British Medical Journal*, January 23, has an editorial in which the regulations governing the conduct of hospital ships are set forth as follows: "It was provided by the International Convention at the Hague that hospital ships should be privileged, and free from attack. The treaty provides that no hospital ship must in any way hamper the movements of the combatants, and during and after an engagement must act at their own risk and peril. All military hospital ships are to be distinguished by being painted white outside with a horizontal band of green about a meter and a half in breadth. With regard to other vessels whose owners assist the wounded, it is provided that neutral merchantmen, yachts, or vessels having or taking on board sick, wounded, or shipwrecked of the

belligerents cannot be captured for so doing. . . . The position of the wounded also is somewhat ameliorated by the treaty, which provides that sailors and soldiers who are taken on board when sick or wounded, to whatever nation they belong, shall be protected and looked after by the captors. The shipwrecked, wounded, or sick of one of the belligerents who fall into the hands of the other are prisoners of war. The captor must decide, according to circumstances, if it is best to keep them or send them to a port of his own country, to a neutral port, or even to a hostile port. In the last case prisoners thus repatriated cannot serve as long as the war lasts."

THE CONSOLIDATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE NEW YORK STATE MEDICAL ASSOCIATION.

The long talked of agreement between the two medical bodies of New York State requires now only mutual endorsement to become a matter of fact. The old society and the New York branch of the American Medical Association have buried all their differences, and have come to a complete understanding. In future there will be but one medical organization in New York State. This happy result has come to pass in the natural order of things, and is a rational solution of an erstwhile troublesome problem.

At the annual meeting of the Medical Society of the State of New York, held in Albany on January 26, 1904, the following resolutions were unanimously adopted: *Resolved*, That the Report of the Joint Committee on Conference be accepted, and that the proposed agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association be and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name and behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereto; and be it further

Resolved, That the committee of the society heretofore appointed for the purpose of bringing about the consolidation, namely, Dr. Henry L. Elsner, Dr. A. Jacobi, Dr. A. Vanderveer, Dr. George Ryerson Fowler, and Dr. Frank Van Fleet, be and they are hereby continued as such committee, with full power and authority to do whatever may be necessary to carry the agreement into effect.

Action on the adoption of the enclosed report, together with the proposal of resolutions ratifying the action of the State Society, will be formally taken at the stated meeting of this society, to be held Monday, February 29, 1904, at 8.15 P.M.

The report referred to above of the Joint Committee of Conference appointed for the purpose of consolidating the Medical Society of the State of New York and the New York State Medical Association has been published in pamphlet form. The entire report covers all details of the consolidation scheme, and has been drawn with intent to meet every point. The result is most satisfactory, and reflects much credit upon the far-seeing perspicuity and common sense of the members of the Joint Committee.

With regard to the constitution of the medical organization of New York State, as it now stands, it is stated "That the membership of the consolidated societies shall include all members of county medical societies now in affiliation with this society, and all members of other county medical societies to which charters shall be granted by the House of Delegates pursuant to the by-laws of this society, and any member ceasing to be a member of a county medical society shall cease to be a member of this society." "The term County Medical Society, as used in this constitution, shall be deemed to include all societies which may be organized and chartered by the House of Delegates." "The membership of the society shall be divided into eight district branches, as provided for in the by-laws."

"The officers of the society shall be a president, three vice-presidents, a secretary, a treasurer, and one councillor from each district branch. They shall be elected annually by ballot for the term of one year, and the majority of the votes cast shall elect. The president, vice-president, secretary, and treasurer shall be elected by the House of Delegates. Each councillor shall be elected by the district branch of the district in which he resides, and shall be the president thereof.

"No delegate elected to the House of Delegates shall be a candidate for office in the society until after the expiration of the term for which he shall have been elected a delegate, and no person shall be elected to any office in the society who shall not have been a member of the society for the two years immediately preceding the date of his election. The constitution of the House of Delegates, its powers and duties, is stated, and the council meetings and funds are dealt with."

There is thus every reason to predict a successful future for the "Medical Society of the State of New York" in its reconstituted condition, and it is quite certain that it is far better for the medical profession to have one united society than two bodies which are not in complete accord.

News of the Week.

The Sanitation of Vera Cruz.—The Mexican Government has determined to make in earnest an attempt to rid its Gulf Coast of the yellow-fever scourge. The Supreme Board of Health has at its disposal $7,000,000 for the work of rehabilitating Vera Cruz, and the greater part of this will be devoted to sewerage and drainage work. The town is divided into four districts, with a medical officer in charge of each. Each one of these medical officers has under him a large corps of sanitary inspectors. A thorough tour of inspection is made of all suspected or infected districts each day, and each evening a report is made of the number of cases in each district. Oil is being used freely. Marshes surround Vera Cruz, and every possible precaution is taken to diminish the number of mosquitos coming from them.

Proffers of Medical Aid in the Russo-Japanese War—The Ministers of Russia and Japan in Washington and the consuls of these countries in this city are in receipt daily of offers of medical aid, but as yet they are unable to accept any. In a recent statement to the press, Count Cassini says that these offers of medical and other aid have become so numerous that he has felt it his duty to bring them to the attention of the Russian Government. It is possible, he thinks, that Russia may find a way to accept some of them, and that American physicians and nurses may aid in caring for the wounded in the Far Eastern war. He is daily expecting an answer from St. Petersburg on this point. The Japanese Government has declined Dr. Senn's offer of his services, but has accepted that of Dr. Anita Newcomb McGee to fit out a staff of nurses. The trained nurses who will go to Japan are self-supporting women, yet they volunteer to serve without any pay. The Japanese Government will provide for them while in Japan, but their own countrymen are asked to supply the cost of their

equipment and transportation. The Knickerbocker Trust Company, 358 Fifth avenue, New York City, will receive and acknowledge all contributions, whether large or small, sent them for the credit of Anita Newcomb McGee, president Japanese War Nurse Fund. A mass meeting of the Finnish and Scandinavian residents of South Brooklyn was held a few evenings ago to inaugurate a movement for the support of an ambulance corps to be sent to the aid of the Japanese wounded in the Far East. A subscription was started for a fund to care for a band of young women nurses who will be sent out within the next three weeks, and also to fit out a hospital ship for naval service. The German Emperor has placed the German naval hospitals at Yokohama and Kiao-Chau at the disposal of the Japanese wounded.

Medical Inspection of Philadelphia Schools.—Forty assistant medical inspectors in the Department of Public Health of Philadelphia have recently been appointed, whose duties, among other things, will include a daily examination of pupils in the public schools, for the purpose of preventing the spread of transmissible disease, and of placing sick children under the care of their physicians. Children suffering from acute disease and all exhibiting symptoms of illness will be sent to their homes, and a systematic examination will be made daily into the physical condition of each pupil until a complete record is obtained of all pupils. Principals and teachers are to set aside daily in a separate room all pupils that in their opinion require medical examination and aid, and the medical inspectors are, so far as possible, to instruct teachers in the symptoms of disease. In addition, the medical inspector is to recommend the medical treatment by the family physician, the district physician, dispensary or hospital, of all children suffering from defects of hearing, deformities, and chronic diseases.

Dr. D. B. St. John Roosa.—A dinner will be given Dr. Roosa at Delmonico's on Tuesday, March 1, to celebrate his twenty-one years of work in the promotion of post-graduate instruction in this country. Dr. William Osler of Baltimore will preside.

Antitoxin Plant for Chicago.—Health Commissioner Reynolds recently visited New York and Newark with a view to making investigations as instructed by the Chicago City Council, as to the practicability and the cost of installing a municipal antitoxin plant in this city. He has not made up his mind absolutely as to the feasibility of such a plant. The cost would depend on the style of plant desired, and it is thought it would require twenty-five thousand a year for its maintenance. The city at present does not sell antitoxin, all that is used being given free in charity cases, subject to a report on the circumstances of the applicant by the Bureau of Charities.

Lost Bequests.—Mr. Benjamin Wood Davis, a well-known Cincinnatian, who died recently, left $140,000 to various educational and charitable institutions, among others $10,000 to the Jewish Hospital of Cincinnati. Unfortunately, the will was made less than one year ago, and therefore these bequests are void under the statutory provision, which requires that a will must have been made more than a year before death, to make such bequests valid.

The New York Eye and Ear Infirmary.—Owing to the lack of funds, it has been decided by the doctors of this institution to close the Platt Pavilion for the treatment of contagious diseases of the eye on March 1. After May 1 no indoor patients will be received, except a few in the DuBois Pavilion, unless a marked improvement in the financial situation takes place before that time. The work in the dispensary will continue as before in any case.

The Administrative Control of Tuberculosis.—The fourth address in the series instituted at Philadelphia by the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis was delivered on February 15 by Dr. Hermann M. Biggs of New York, who discussed the measures to be instituted, in order to secure municipal control of tuberculosis. The first essential is compulsory notification and registration of all cases. This has an educational value over and above their usefulness in other directions. At first resented in New York and deemed impracticable and inexpedient, they have yearly increased in favor, Dr. Biggs said, until at present the returns are fairly complete. The reports are considered as confidential, and action is taken by the Board of Health only when the attending physician makes the request, or there is none in attendance, or the patient is under the care of a public official. When necessary instruction is given by personal visit and by printed circular as to the nature of the disease and the means of its dissemination, and also of the measures required to prevent the latter. In case of death or removal appropriate disinfection must be instituted. Cases that cannot properly be cared for at their homes, or that are a menace to their surroundings, are removed to hospitals. In the campaign against tuberculosis a dispensary service is necessary, providing not only professional attention, but also medicines and food. Visits to the homes of patients should be made by physicians and trained nurses, in order that necessary aid may be given, and information obtained as to the relations of the patients to others. A special hospital is required for advanced cases that cannot properly be cared for in their homes, and to which, if the circumstances demand it, patients should be removed, even forcibly. There should be at the command of the health department also sanatoria for the care of the less advanced cases of the disease. Among the duties of the department should be the examination, gratuitously, for tubercle-bacilli of all sputum submitted to it. A record should be kept of houses in which cases of tuberculosis occur, and when the disease occurs with noteworthy density, steps should be taken to correct the underlying faulty conditions. Much has been done by the New York Department of Health along the lines indicated, with the result that each year an increasing number of cases is being reported, but most important of all, that a noteworthy reduction in the mortality of the disease has been effected. That this latter is not due to an increased mortality from pneumonia, real or otherwise, as had been suggested, was shown on a special investigation. Dr. Briggs showed by diagrams the number of cases in some houses in the congested districts of New York, and stated that in certain instances properties have been condemned on this account, while the conversion of portions of some such districts into public parks is contemplated.

A Seaside Hospital for Surgical Tuberculosis.—The New York Association for Improving the Condition of the Poor has appropriated $15,000 for the maintenance at the seashore next summer, of children under fifteen years of age suffering from the non-pulmonary manifestations of tuberculosis.

Many Bequests to Charities.—Louis Gans, who during his lifetime gave liberally to charity, left a will, filed for probate, making bequests to a large number of religious and charitable institutions of this and other cities. The will includes the following gifts to

New York institutions: Montefiore Home, $25,000; Mount Sinai Hospital, $2,500; United Hebrew Charities, $2,500; Hebrew Sheltering Guardian Society, $2,500; Hebrew Orphan Asylum, $2,500; Jewish Theological Seminary, $2,500; Home for Aged and Infirm Hebrews, $1,000; Beth Israel Hospital, $1,000; Lebanon Hospital, $1,000, and the Colored Orphan Asylum, $1,000.

Disease at the University of Minnesota.—It is possible that the Minnesota State University may be closed for the remainder of the scholastic year, because of the continued prevalence of typhoid fever and diphtheria. A veritable epidemic of typhoid fever is feared, and the students have been repeatedly warned against the use of the city water unboiled. A faculty health committee has been appointed and everything possible is being done to prevent the further spread of disease.

Dr. William C. Sebring of Kingston, N. Y., has been appointed attending neurologist to the Benedictine Hospital in that city.

Another Cancer Cure.—In a paper read before the Paris Academy of Medicine on Monday of this week, Dr. Doyen announced that he had elaborated a curative serum for cancer. This serum was prepared in the usual way from cultures of micrococcus neoformans, which the speaker regarded as the pathogenic microbe of carcinoma. Of one hundred and twenty-six patients treated in two years fifty-eight did not show favorable results, forty-seven improved in varying degrees and twenty-one presented no evidence whatever of cancer and were regarded as cured.

The German Polyclinic at 78 and 80 Seventh street in this city is to be enlarged by the addition of a two-story rear annex, 50 feet front and 35 feet deep, making the building 125 feet deep. The annex is to be fitted as dispensary operating rooms.

Carbolic Acid and Suicide.—It would seem that the use of carbolic acid is not a passing fad among suicides, but an established custom, due primarily to the fact that the legitimate uses of the acid are so numerous that it is easy for almost any person to give a druggist a plausible reason for the purchase of it. The Retail Druggists' Association of Chicago favors the passage of a city ordinance regulating the sale of this poison. It is said that the placing of restrictions upon the free sale of concentrated solutions will do much good, with little inconvenience to the public, inasmuch as more diluted solutions are satisfactory for most legitimate uses. The concentrated solutions are fatal, but the weaker solutions are much less dangerous. A properly framed ordinance would doubtless reduce the number of suicides.

Pneumonia and Typhoid Fever in Philadelphia.—For the week ended February 20, there were reported to the Philadelphia Bureau of Health 605 deaths, of which 125 were due to pneumonia. There were also reported 142 cases of typhoid fever.

The Chemical Laboratory of the Ohio State University at Columbus was totally destroyed by fire February 19. The loss is estimated at $100,000, of which $75,000 represents the value of the building, and $25,000 the equipment. There is no insurance.

Licensing Refractionists.—The first State examination for license to practise optometry in California was held at San Francisco February 1 and 2. The applicants represented, numerically at least, only a small ratio of those who have been in practice without the formality of a license.

Ratification of the Plans for Medical Unity.—At the meeting of the Medical Society of the County of New York to be held Monday, February 29, action on the adoption of the report of the joint committee of conference, together with the proposal of resolutions ratifying the action of the State Society, will be taken. Ratification of the action of the State Society by each county society is requisite for the completion of the consolidation.

Radium.—Consul-General Guenther reports from Frankford, Germany, that notwithstanding the difficulty in its production (many tons of ore being required to produce one gram) a radium industry has already developed in Germany and France, and although the price of one gram is about $2,000, the manufacturers are said to have orders for several hundred grams.

Vital Statistics of France.—Thornwell Haynes, Consul at Rouen, France, states that the *Journal Officiel* has recently published a report on the population of France during the year 1902. The births were 845,378 and the deaths 761,434, an excess of 83,944 births over deaths, against 72,398 in 1901. This result is due to a notable diminution of mortality, as there were 11,896 less births and 23,442 less deaths than were recorded in 1901. There were 291,431 marriages and 6,895 divorces last year.

Preparing for the Mosquito War.—A bill has been introduced into the New Jersey Legislature by Assemblyman Edward D. Duffield of South Orange, and is now in the hands of the Committee on Public Health of the Assembly, which is designed to afford boards of health additional power in the matter of mosquito extermination. The bill defines as a public nuisance waters in which mosquito larvæ develop, and empowers local boards of health to compel owners of land on which there is such standing water to abate the nuisance.

Examination for the Marine-Hospital Service.—A board of officers will be convened to meet in Washington, D. C., Monday, April 4, 1904, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service. Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The following is the usual order of the examinations: 1, Physical 2, Oral. 3, Written. 4, Clinical. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars, passed assistant surgeons, two thousand dollars, and surgeons, twenty-five hundred dollars a year. When quarters are not provided, a commutation at the rate of thirty, forty, and fifty dollars a month according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, 10 per centum in addition to the regular salary for every five years' service up to 40 per centum after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed

ctual expenses. Further information may be btained by addressing the Surgeon-General, Public ealth and Marine Hospital Service, Washington, . C.

Obituary Notes.—Dr. JACOB RAPELYE LUDLOW of aston, Pa., died of pneumonia at his home in that ty on February 10. He was born in Somerset ounty, N. J., in 1825, and was graduated in medi- ne from the University of Pennsylvania in 1845. e first practised in Neshanic, N. J., but removed to aston in 1850. He served with distinction through- t the Civil War in the medical corps of the Union rmy, and at the close of the war settled in Knox- lle, Tenn., where he remained for fourteen years, 1879 he returned to Easton, where he practised to about five years ago, when he retired from tive work. A daughter and two sons, one of whom a physician, survive him.

Dr. JAMES P. RICHARDSON of San Francisco died that city on February 9, at the age of eighty-four ars. He was a native of New York State, and was aduated from the Medical Department of Colum- n University, Washington, in the class of 1886.

Dr. HENRY MARTIN DEARBORN, a homœopathic actitioner of this city died of pneumonia on Febru- y 16, at the age of fifty-eight years. He was born Epson, N. H., and was graduated from the Bow- in Medical School in the class of 1869. He was rmatologist to Flower Hospital, Laura Franklin ee Hospital for Children, Manhattan Hospital and . Mary's Hospital of Passaic, N. J. He was also ofessor of dermatology at the New York Homœo- thic Medical College, and the New York College d Hospital for Women. He was a former presi- nt of the Homœopathic County Society, and was a ember of very many local and national homœo- thic societies.

Dr. JAMES MADISON LAIRD of Mt. Carbon, W. ., died on February 16, following an operation r an abscess on his neck. He was a native of rginia, but had practised his profession in West rginia for about thirty years. He was educated Hampden-Sydney College, Virginia, and studied edicine at the University of Virginia, and at the niversity of New York, from which latter insti- tion he was graduated in 1877. He was known er a large section of West Virginia for his in- lligence and skill, and his kindness to patients in ouble won for him a large circle of grateful friends.

Dr. WM. F. BUCHANAN died in Philadelphia on ebruary 16. He was a graduate of the medical epartment of the University of Pennsylvania, d enlisted as an acting assistant surgeon in the nited States Army in 1862, being attached to the xty-eighth Illinois Volunteers until 1864, when was appointed assistant surgeon, and was made xecutive officer to the Medical Director, and later ssistant Medical Director, Department of the outh. After the Civil War he was surgeon at Fort eavenworth and Denver, and with the Thirteenth nited States Infantry at Lexington, Mo. He as with General Hancock's Indian expedition, nd later was stationed at Fort Harker, Kan. In 867 he was breveted captain for meritorious ser- ices during the Civil War. He was stationed at estern forts until 1867, when he resigned.

Dr. ALVIN R. DAVIS died at Rawlins, Wyo., on ebruary 16. He was a graduate of Jefferson edical College and had formerly resided at Dover, el.

Dr. S. J. SEYFERT died at Pinegrove, Pa., on ebruary 14 at the age of sixty-six years. He as graduated from the Medical Department of the University of Pennsylvania in the class of 1871.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ARMY MEDICAL COLLEGE—HOUR-GLASS STOMACH—PELVIC LESIONS IN RELATION TO ABDOMINAL DIAGNOSIS—PAIN IN DIAGNOSIS—MR. BALFOUR—ROYAL COLLEGE OF PHYSICIANS.

LONDON, February 5, 1904.

THE eighty-eighth session of the Royal Army Medical College opened yesterday, when Sir Wm. Taylor delivered an address to the lieutenants on probation. He said the course of post-commission study, now happily provided for, rendered the establishment of a military-medical teaching institution in the metropolis essential. The closer the union between the military and civil members of the profession, the better he thought it must be for the State and the army medical corps. One of the objects of the college, and that not the least, was to be a center toward which, for imperial purposes, the medical military profession at home and in the colonies should converge—the auxiliary as well as the regular services. This college should have far-reaching beneficial results, both to the civil and military branches of the profession. "You will sometimes hear it said," continued Sir William, "that the army doctor has little to do. Let not that disturb you; you will find from experience that it is otherwise. It is also said that his practical experience is confined to treating the diseases of early manhood, and that this limitation of practice leads to stagnation of effort and to blunting of mental acuteness and judgment. Believe me there is nothing further from the truth. No army medical officer need let his knowledge rust. There is abundance and variety of clinical work to be found in our army hospitals. The field of the army surgeon is world-wide, and in the domain of tropical medicine he will find a field of observation and research that afford opportunities for practice and progress that no other section of our profession possesses." Sir William went on to show what work had been done in the school during late years, in relation to typhoid fever and the attempt to restrain its ravages by inoculation. The prevention of this disease, he asserted, was of momentous importance in army sanitation—the most momentous at the present day. So was that of the allied disease, dysentery, and much of the recent work on that had been done by their officers. In conclusion, Sir William said that to recount the work of the officers trained in that college would be almost to write the history of tropical medicine, and so he would close "by mentioning the name of Major Ronald Ross, the discoverer of the etiology of malaria, who received his training in hygiene and pathology in their school."

An important paper by Mr. Moynihan on "Hour-glass Stomach" was read at the Medico-Chirurgical Society on the 26th ult. He rejects the idea that some cases may be congenital—not a single trustworthy record of such an occurrence being known. On the other hand, in addition to recognized causes, he admits constantly recurring spasm. He has witnessed severe spasm during operations and considers it likely to lead to hyperthropy of the circular muscular fibers. Washing out the stomach with a measured quantity of fluid, and noting the quantity that is returned, affords the most reliable indications. If washed till the return fluid is clear, a sudden rush of foul-smelling fluid following is significant. If, after the stomach has been washed clean, the tube is repassed in a few minutes and a quantity of offensive fluid comes, this again is significant. These two are Wölfler's signs. Succussion on palpation may be noted; if then the tube be passed and the stomach apparently emptied, a splashing may still be elicited. If the stomach be distended up to bulging of the left epigastric region, this will gradually subside, and bulging of the left side appear; when sizzling of bubbling may be heard through a stethoscope. So the stomach may be distended with air and give enormously increased resonance of the upper part while the lower part remains without alteration. In many cases there is a narrowing, not only in the body of the stomach but also at the pylorus, so that no one operation can meet every case. Mr. Moynihan mentioned the different procedure he had had to adopt. The president, Mr. Willett, remarked that in London there were not nearly so many cases as in the north, and asked if anything in the habits or neighborhood had been observed predisposing to the complaint. Mr. Moynihan said he could offer no explanation of this, and in reply to other questions added that his operations were aseptic, and he thought the mortality would be less but for the previous years of suffering, which reduced the strength of most patients.

Dr. Handfield Jones opened a discussion at the Medical Society on pelvic lesions in relation to abdominal diagnosis. He referred to the gastric irritability which is

so common in metritis and endometritis and the question which often arises as to whether a gastric ulcer has perforated or a gravid tube ruptured. Exploratory laparotomy could decide, and was the only plan in many cases, when the signs were very doubtful. Abdominal and pelvic lesions might coexist, and the diagnostic difficulties would then be aggravated. Some cases of the kind were mentioned. Pelvic adhesions might give signs of abdominal mischief.

Mr. Doran alluded to various points, such as uterine vomiting, menstrual nausea and faintness, menopause symptoms, hemorrhages, tubal pregnancy. He said, too, pelvic tumors of non-pelvic origin were deceptive, *e.g.* pelvic kidney. Lumbar tumors in women might be ovarian cysts with twisted pedicle.

Dr. Heywood Smith thought the mammary symptoms in a primipara might help diagnosis in early extrauterine pregnancy. Tenderness between an inflamed appendix and the pelvis could sometimes be made out.

Dr. V. Bell described a case of apparent intestinal obstruction which proved to be a parovarian cyst.

Mr. Owen alluded to the cases of recovery after laparotomy when nothing was found. He mentioned vaginal discharges of dark blood as a sign of tubal pregnancy.

The President, Dr. de H. Hall, described a case of supposed appendicitis which proved to be one of strangulated ovarian cyst.

Pain is always an interesting subject from whatever point of view it is considered, and it is one with which the doctor is constantly engaged, but which neither he nor the patient profess to understand, while the philosopher can speculate gaily on the mystery—always provided he is not suffering.

Mr. Bowlby had, therefore, a popular subject and a good audience at a lecture on pain and its importance in diagnosis and its tendency to mislead. If he had not much to offer that was new to the members of the Hunterian Society, he could at least set before them in good order some useful reminders. I pass by what he had to say of the utility of pain, and leave to the philosophers the proof that it is essential to the preservation of the body, and as Mr. Bowlby alleges, to every separate tissue.

It may be so—but the statement is capable of being disputed.

The varying value of pain as a symptom is familiar to all, and Mr. Bowlby gave good illustrations of this. In children, he said, "growing pains" and so-called rheumatic pains may be indications of tuberculous bones or joints or other grave diseases. At the other extreme of life pain is often slight in comparison with the exciting cause: strangulated hernia or urinary calculus are sometimes examples. Some dull, stolid people complain of no pain in conditions which excite the strongest expressions by more sensitive persons. Neurasthenic pain may be seen in men debilitated by disease, by accidents, mental distress or overwork, indulgence in stimulants or narcotics.

Mr. Bowlby illustrated his subject by some of his experiences in the South-African War. Speaking next of "referred pain," he warned his hearers not to diagnose hastily sciatica, which he had known to be credited with the pains subsequently proved to be due to sarcoma of the ilium, cancer of the femur, tuberculous abscess in the gluteal region. The frequency with which pain originating in the intestines is referred to the umbilicus was mentioned by Mr. Bowlby, who had observed that in early cases of appendicitis this was often the case, or the pain in these cases might seem to be general. He thought probably the appendix hung free in such cases, but when adhesions had been formed to neighboring parts the pain would be localized. A little discussion followed in which Dr. G. Lyon referred to the sensitiveness to pain of the Semitic races, and Dr. J. Adams compared Jews and Indian fanatics. He referred also to the absence of pain sometimes met with in cancer, etc. Dr. Arthur Davies related a case of aneurysm which eroded the vertebræ but produced no complaint of pain. He made the sensible suggestion that doctors should be careful not to suggest pains of any kind to their patients. Dr. Goodall mentioned the abdominal pain which sometimes obscures acute pneumonia. Dr. L. Brown mentioned Mr. Barnard's opinion that abdominal pain in chest cases indicates that the diaphragm is affected. He also mentioned a case of extreme pain in the head which was never explained. Mr. Hosford referred to painless multiple aneurysms. Mr. Bowlby replying to these remarks said Semitic patients often puzzled surgeons by unaccountable rises of temperature as well as by pain. He expressed the opinion that sensitiveness to pain increases with the development of the intellectual faculties.

The absence of the Prime Minister from the opening of Parliament on account of illness preduced a depressing influence among all parties, for Mr. Balfour is personally a great favorite with opponents as well as supporters. His attack of influenza is pursuing a favorable course, and the last bulletin is encouraging.

Dr. Geo. Oliver has given £2,000 to endow a lectureship at the College of Physicians on the application of physiology to the prevention and cure of disease and the prolongation of life. Dr. Horace Dobell has given the same college £500 for a biennial lectureship on researches by the lecturer on pathogenic microorganisms.

PURE WHISKEY.

To the Editor of the Medical Record:

Sir: Your editorial of the 6th inst., "Relating to Whiskey," is most timely, since the subject is before a committee of the United States Senate.

This is a time when the medical profession can presumably be instrumental in the accomplishment of incalculable good.

It should insist that the original feature of the Hepburn bill be retained, which was that the public should know the composition of the whiskey which it uses. Not that all blended whiskey is to a degree poisonous, but the uses of whiskey are too broad, and the profession should demand an act of publicity. Otherwise, I judge, that the so-called rectifier or compounder will be accommodated in the matter of secrecy for two reasons. A committee from the rectifiers recently received a promise from Dr. H. W. Wiley, Chief of the Bureau of Chemistry, that he would raise no objection to the suggested amendments to guard against any possibility that under the bill the disclosure of formulas would be required. Dr. Wiley is quoted as saying that "some perfectly honest, upright gentlemen are engaged in the business, and they do not want these things to get out of their hands to be used for fraudulent purposes." So well and good for these gentlemen, but most unfortunately by their example, or otherwise, the market is amply supplied with the "essence of whiskey, etc.," which are added to the often embruting compounds. The chemistry of these things is known only to their concocters. It is probable that their base is fusel oil! If not, the pathological effects of the average essence, or ether, are well known. For when used alone, in the quantity in which whiskey is used, such use may cause death within a few hours. "French spirits" are used by certain rectifiers. As to essence, three men died in Raleigh Co., West Va., as the result of drinking the essence, or the oil of cinnamon, or peppermint. And this is a not uncommon cause of sickness, and sometimes of death, in the prohibition counties of West Virginia. The three men were reported to have died before medical aid reached them, and death was preceded by agonizing pain.

So it becomes the medical profession to look to Congress, and to beseech it that the poisoning and the occasional maddening of its citizens through compounded, blended, undistilled liquor, shall cease. And the good rectifier is too much like the good Indian. There is enough good whiskey distilled in this country.

Thos. R. Evans, M.D.

Deepwater, W. Va.

SHALL THE GENERAL PRACTITIONER DIVIDE FEES WITH THE CONSULTANT?

To the Editor of the Medical Record:

Sir: The question of dividing fees between practitioner and consultant has been quite exhaustively discussed from different points of view. Vindex is probably right in what he says should be the equitable basis of reciprocal relations. He probably enjoys a large practice, and is secure enough in his position not to fear the men who may envy him or may try to supplant him. The majority of medical men are not so situated. With the youngsters especially it is a struggle long and hard to get a foothold. One trouble is that the specialists are too numerous and must make strenuous efforts to succeed. In fact, they must get business, no matter in what way. The army of young surgeons, for instance, must do or die. It is these chaps, together with the gynecologists, who are responsible for the introduction of the so-called "graft" system of surreptitious fees. They must divide up or starve. They must bid for trade or quit. Hence, they are willing to operate for the smallest possible fees rather than not be busy. They make it an object for their friends to send them cases. They cannot return favors by recommending patients not in their line, and hence money comes in to strike the balance. They have taught the family attendant to expect commissions, and now the operator who does not respond in kind is not called again. Of course, all this is done slyly, and, as one of your correspondents says, "it is nobody's business." The innovators train in groups and form little cliques for self-improvement. They found little societies, read papers,

and work into each other's hands as secretly and loyally as they did formerly in their college fraternities. They do not bid openly by offers of money, but send little checks as presents afterward. It is the share for the good friend who thinks of them at the right time. Some of the physicians who have cases to sell are in the habit of writing to operators, asking the amount of the commission for the case. Every surgeon in active practice knows this. It is done in town and out of town. Personally, I have lost more than one good case because I refused to be party to such a bargain. The older specialists are the sufferers in this regard, because they are left behind by the new methods. Verily, competition is descending to the "knockdown and drag-out system," and is as difficult to modify or control as any other secret or underhanded element of modern depravity. How are we to reach men who are bound by such strong and mutual ties? The men who make the bargain stand facing each other with open arms.

Expert fees are thus not only relatively but are positively lowered. Every man who graduates as house surgeon of a hospital is ready to do any operation—or at least he thinks he is—for the smallest possible pay. Oftentimes half of this goes to the man who sends him the cases. They can afford to do this rather than nothing. At this rate the profession is skimming its own milk, both at the bottom and the top.

HOSPITAL SURGEON.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Presumably some of your correspondents upon this subject are more or less veiled humorists. The desire of "specialist" to obtain some general opinion on this "vital subject," and the pains which a prominent New York surgeon has taken to clearly and succinctly set forth the true *moral* aspect of the matter, especially in connection with the routine practice in $10,000 gall-bladder cases are much appreciated here in the West, where such cases are peculiarly troublesome, and a daily source of worry to those interested in this "vital subject." But our conscientious brother's views, also expressed in the MEDICAL RECORD of February 6, p. 225, though on the surface remarkably clearly and practically set forth, leave one somewhat uncertain whether he is a medical Mark Twain, or a rare soul wholly devoid of self-interest. He might do in theory, but is most too generous and just (to himself) for effective practice in an imperfect age of graft. Grafting is still a very imperfect science in America, and probably capable of much improvement.

That the question certainly has considerable interest to a portion of the profession, is shown by the occasional letters of inquiry which the specialist receives as to what his present percentage may be, or as to whether he would be willing to do better than Dr. Blank, who only pays 33⅓ per cent. That it possibly has a moral aspect, has until recently been generally conceded, and certainly questioned least of all by the grafters, who, on the quiet, might admit having resorted to the practice, but never feel like boasting about it. At any rate discussion of the moral aspect would seem more appropriate to the primary Sunday school than to adult professional gentlemen. There is probably only one aspect of the question that would seem to be of much practical importance, and that is, is it expedient, does it pay? In considering this momentous question, there are naturally three points of view, aside from the "vital interest," the "moral," and "the conscientious."

First, there is that of the so-called general practitioner: either he has rendered the patient a service for which he should be paid, or he has not. If he has rendered such a service, is it for his best interests to have his fee collected indirectly by another, the patient supposing him to be laboring gratuitously? From every viewpoint —no. No man with a good business head or much self-appreciation would allow himself to be put in such a light before his patients whether he has any morals or not. If he has rendered no services, neither the $10,000 proposition nor any personal peculiarity of conscience seems capable of demonstrating why he should receive any fee directly or indirectly.

Second, There is the view point of the specialist. Unless he wishes to be the abject slave of the meanest tyrant, he will not attempt to buy the influence of the general practitioner. He will find it much cheaper, more independent, and pleasanter to appeal directly to the public. In the first place, he will find that the best and most influential practitioners cannot be bought, but only their contempt incurred, and, second, that the yellow curs that he can buy are rarely long worth the price; they will soon raise the price on him and surely fall out with him over the division of the spoils. The influence of men of this caliber is not often great and is notably erratic.

Third, there is the viewpoint of the patient. Living, as he does in this era of graft, he is not long in getting wise to the game, he is not half as scandalized or shocked as the profession as to the moral side of the question. because he is in these days practised upon from too many directions, and he has learned not to expect all that dealers in gold bricks and such like claim. He simply avoids the tariff, or tries to, in taking precautions in choosing his own general practitioner and his own specialist.

So in the end nobody is badly fooled or very much hurt, and the vital question of dichotomy will gradually work itself out. That it will entirely disappear is not more likely than that many other sharp practices will do so. Some of the pioneers in this field made a brief stake, but just at the present the trade is too limited, and competition too great to make it worth while, except in a small and occasional way. The question is not really so vital after all as some appear to think. It may be sometimes cunning, but never wise. Lord Bacon truly says, "Certainly, there is a great difference between a cunning man and a wise man, not only in point of honesty, but in point of ability."

Cholecystostomy and Cholecystectomy: A Study of a Series of Operations.—Charles L. Scudder formulates his opinion in regard to these operations as follows: Cholecystostomy should be done in those cases of gall-bladder and biliary duct surgery in which quick drainage is needed for the deeper ducts and in which the surgeon is not absolutely sure that the deeper ducts are entirely free. Cholecystectomy should be done in cases of acute cholecystitis, in cases of cholecystitis resulting in gangrene and empyema of the gall-bladder, in small contracted (infected) gall-bladders which are functionally useless and which will not be of service in facilitating drainage, and in all cases in which the surgeon is morally sure that the deeper ducts are free from obstruction. The writer believes that during an acute attack of gallstone colic it is wise to postpone operative interference. Operation should be performed in any case showing definite signs of gallstones or an inflammatory process about the gall-bladder. In general, the earlier the operation, the better. An interesting series of sixteen cases is presented at the conclusion of the paper.

Remarks upon Cholecystectomy and Cholecystostomy, with Special Reference to Their Comparative Safety and Efficiency in the Treatment of Biliary Affections.—Maurice H. Richardson declares that in many cases there can be no choice between cholecystectomy and cholecystostomy. The gall-bladder is already practically extirpated, and in many cases its condition is such that it must be extirpated. Choice exists only when the gall-bladder is comparatively normal. The writer gives several practical arguments in deciding between the extirpation and drainage of the gall-bladder. He first compares the dangers of the two operations. Clinical experience shows that cholecystostomy is the safest of all operations upon the biliary passages. The writer assumes that extirpation of a normal gall-bladder is almost but not quite as safe as cholecystostomy. If there is any choice on the ground of immediate danger, it is in favor of simple drainage. There are conditions in which drainage is quite as dangerous as extirpation—that is, when the gall-bladder is deeply contracted, hard to find, adherent to surrounding viscera and infected. The comparative dangers between these two operations are chiefly in connection with the normal and the comparatively normal gall-bladder. The prevention of gallstones is next discussed. The writer believes that the argument of preventing gallstones by removing at once the *fons et origo mali* is a very strong one, and weighs almost wholly in favor of cholecystectomy. He is convinced that as a rule gallstones are formed in the gall-bladder, and there alone. As to drainage of the biliary passages, the writer believes that cholecystectomy without drainage is an incomplete and dangerous operation; and that cholecystectomy with drainage of the hepatic duct is an unnecessarily dangerous operation when cholecystostomy is so very easy and so safe. Biliary drainage through anything but the gall-bladder is very risky—not to mention the danger of the operation itself. Cholecystectomy seems an operation of last rather than of first resort—for old, infected, useless gall-bladders through the remains of which temporary drainage may be easily and safely established. The most important objection to

extirpation of the gall-bladder, when the cystic duct is ligated, is the loss of those great benefits which follow prolonged drainage of the biliary passages.

Journal of the American Medical Association, Feb. 20, 1904.

A Clinical Note on Obscure Cases of Septic Fever.—L. F. Bishop refers to cases which are of obscure origin but suggest a septic infection. The temperature, which is the principal symptom, runs an irregular course and is sometimes preceded by slight chills. There is a certain loss of flesh and strength. It is difficult to exclude tuberculosis, typhoid fever, and malaria. Recovery pretty regularly takes place, but there is an occasional fatality, causes having been, in the author's experience, malignant endocarditis, acute pleurisy, and exhaustion. In these cases Bishop advises forced feeding (especially milk and eggs) and a moderate amount of alcoholic beverages and tonics.

Ectopic Pregnancy.—F. F. Laurence refers to several cases. In one, a woman of twenty-six years, ectopic pregnancy occurred twice within fourteen months. Two other cases are referred to. Laurence emphasizes the dangers of leaving a Fallopian tube behind at the time of operation for rupture of the other tube. He calls attention to the fact that ectopic pregnancy occurs in a normal condition of the uterus and tubes; that there is always a preceding tubal disease; that the particular form of tubal disease, viz., desquamative salpingitis, is bilateral; that there is practically always an accompanying localized peritonitis affecting the tubal covering; that the consequent probability of a normal pregnancy is slight; that the danger of an unrecognized or unsuspected tubal gestation cannot be estimated; that extra-uterine pregnancy may go to rupture before it is suspected, and that ruptured ectopic pregnancy is very apt to be fatal.

The Early Signs of Pregnancy.—H. L. E. Johnson calls attention to an early sign of pregnancy to which he attaches great importance. It is observed as early as the fourth week, or possibly earlier, and consists of an intermittent softening and hardening of the vaginal portion of the cervix uteri with, in many cases, a change of color, from a pale violet to the normal pink hue, or the reverse. These changes in consistence and color are rhythmic, more or less. The alternate softening and hardening is easily detected by digital touch, while changes in color may be seen through a speculum. These signs or processes are, in all probability, early manifestations of what is subsequently recognized as the intermittent contractions of the pregnant uterus, and are probably due to a necessity for some change or modification in the uterine circulation incident to the nourishment and growth of the impregnated ovum through physiologic intermittent congestion of the generative system.

The Ocular Complications of Bright's Disease.—These are discussed by L. Stricker, who gives the histories of several cases illustrated with diagrams of the retinal findings. His general conclusions are as follows: (1) There are no ocular complications of Bright's disease from which, independently, a positive diagnosis of Bright's disease can be made. They should direct our attention to the probability of Bright's disease and lead to systemic examination. (2) The prevalent idea that one must find the characteristic picture of Bright's disease with hemorrhages and areas of degeneration and white splashes in the region of the macula, is a mistaken one, since one may meet with any of the many manifestations of vascular or retinal inflammation due to the action of toxins. (3) Only a small percentage of cases of Bright's disease develops ocular complications, but if larger numbers of cases were systematically examined it is more than probable that a much larger percentage would be found to have ocular lesions, which have not caused functional disturbances, and consequently have been overlooked. (4) All the ocular complications of the disease are the result of altered nutrition, or toxæmia; in other words, a chronic uræmia. (5) Diseases of the eye coming on in the course of Bright's disease are of the most serious prognostic import, and indicate an early dissolution of the patient. (6) In the acute form conditions are of a more hopeful character, though a prolonged siege, with inability to stay ocular disease, cannot fail to leave the patient, though he recover, with greatly impaired vision. (7) An estimation of the urea quantity made from a total amount of the urine of twenty-four hours, under proper diet, is the barometer by which we are to be guided in determining the early or immediate fatal outcome of the case. (8) In the Bright's disease of pregnancy, with ocular involvement, a low urea quantity should be a positive sign for immediate interference, and should justify artificial abortion both to save the eyesight as well as the life of the mother. (9) In cases of Bright's disease disclosing choroidal and retinal changes, he has found the urea quantity in the urine below the normal; and it seems more than probable that the urea or other excrementitious substances retained in the blood, due to faulty kidney excretion acting as chemical irritants or toxins, are directly responsible for the inflammatory or degenerative changes.

Medical News, February 20, 1904.

Case of Tetany.—Joseph Barsky reports this case. The patient was a girl of eleven months. The family history was negative. The present illness began suddenly. The writer, after examining the child, found the usual symptoms of tetany present. It is characteristic of the disease that it is always bilateral, with symmetrical contractions, some time of variable intensity on either side. The writer does not believe that tetany is always a complication; it may be the initial symptom of any of the acute febrile diseases. The etiology is obscure. Boys are more often affected than girls. Gastrointestinal disorders seem to be the main etiological factors, but in this present case the tetany seems to have been the symptom ushering in an acute bronchitis which lasted four days, and from which the child made a complete recovery. Nothing is better for the rigidity than a warm bath. Pain is relieved by the application of cold to the involved joints and the internal administration of the bromides and antipyrin. In rare instances of asphyxia, chloroform inhalations should be given.

House Infection of Tuberculosis.—Lawrence F. Flick declares that the most striking feature about the communicability of tuberculosis is that it depends almost entirely upon the house. An enclosure of some kind is so necessary for the conveyance of the disease from one person to another that contagion is impracticable without it. Implantation of the tubercle bacillus greatly facilitated by the house. The house prepares soil for the tubercle bacillus. This bacillus cannot get a foothold in perfectly healthy, normal tissue. In the beginning of the tuberculous process the tendency to recovery is so great that the slightest aid to nature may turn the tide toward recovery. The large death rate from consumption really must be ascribed in a great measure to bad ventilation in home and workshop. The last stage of conflict between this disease and its victim is the house. Tuberculosis develops into consumption because of the house. Tuberculosis in itself would seldom prove fatal if the patient lived out of doors. Life in the open air greatly retards the development of tuberculosis and promotes recovery. The house makes and maintains consumption, and consumption kills. It is well termed a house disease. Without the house it would not exist. It depends upon the house for its implantation, propagation, and for evolution of all its phenomena. In the house the tubercle bacillus lies dormant in wait for its new host. Whatever shuts out fresh air, shuts out health and happiness. In house-infection is the key to the entire problem of stamping out tuberculosis.

New York Medical Journal. February 20, 1904.

Osteomyelitis.—Seventeen cases are reported by Howard Williams. The disease is essentially a germ infection, though not a specific one of bone tissue, for the exciting microbic cause may be any one of the pus-producing organisms. The septic process is almost exclusively a disease of the period of bone development and growth, beginning with but few exceptions in the growing tissues at the end of the diaphysis near the epiphyseal cartilage on the side remote from the joint in childhood. Trauma usually plays the rôle of the exciting cause. The malady is most frequently confined to the long bones. The constitutional symptoms are the classical ones of sepsis. Local signs include muscular spasm or contracture, redness over the skin, œdema of the deep subcutaneous tissues, and a central swelling or thickening, an œdema of the peritoneum felt on deep pressure. Later comes fluctuation. Differential diagnosis is called for from deep cellular abscess, erysipelas, typhoid fever, and acute rheumatism. Treatment is purely surgical. Delay means disaster. Early intervention saves patients from disfigurement and permanent disability. If nature forms an involucrum around a necrosed section of bone, sequestrotomy is then indicated. The last resort is amputation. If the disease occurs at either the shoulder or hip-joints resection will generally lead to a fairly good functional result.

The Clinical Importance of Aërophagia.—H. Stern discusses the question of aërophagia (air-swallowing), enumerating as the symptoms gastric oppression and eructations. Sometimes the air accumulates in the œsophagus and does not enter the stomach at all. If the latter becomes distended we may expect anxiety, dyspnœa, sense of suffocation, palpitation, headache, vertigo, anorexia, vomiting, emaciation, and general debility. In the worst cases symptoms are referable not

only to the stomach but to portions of the digestive tract lower down, and the symptoms then produced have been mistaken for those of typhoid fever, appendicitis, and enterocolitis. Many cases occur among drivers, riders, and automobilists. In cases of habitual swallowing of air, rest and sleep are of the first importance, and lavage is generally beneficial. Dietetic treatment is useless, and by constantly calling the patient's attention to his affection may perpetuate the condition it is designed to cure. When practicable a tube may be used to facilitate the exit of air, and its use should be followed by irrigation with six to eight litres of water at 43° C., to which a little chloroform water has been added. Internally such remedies as menthol and bismuth are of service. When the air accumulates in the small intestine, no solid ingesta should be allowed till the bowels have been completely evacuated. If pain is severe, opium may be necessary, and may be given in a suppository combined with belladonna. Other remedial measures include rest in bed and hot fomentations. Massage may often prove injurious to the patient.

American Medicine, February 20, 1904.

The Retinal Symptoms of Vascular Degeneration.—L. W. Alleman believes that it is but reasonable that if functional alterations precede organic changes in the circulatory system, they should be discoverable in the eye, where alone in the economy it is possible to inspect a vessel without interfering with its function. The physical condition which gives rise to the first evidence of disturbed nutrition, visible in the fundus oculi, is a high peripheral tension dependent upon or associated with improper elimination. There are no constant general symptoms characteristic of slight nutritive disturbances. In many cases the patients believe themselves to be in the best of health. But there is usually a history of overwork or worry at a time shortly preceding the examination, or of intemperance in food, over-stimulation, or a neglect of reasonable physical exercise. The writer considers four groups of cases: In the first group no organic lesion is discoverable by the ophthalmoscope. The important finding is a tortuosity of the smaller retinal vessels and of their terminal twigs. In the second group of cases, a similar condition of the fundus is found, but in addition more or less bending of the vessels at the crossings is present. In many cases a change in the caliber of the retinal vessels is observable. Another retinal symptom is a momentary decrease in the force of the retinal circulation. In the third group of cases, some evidence of organic change in the vascular walls can be made out. In the fourth class, the cases presenting advanced vascular disease are included. The one constant abnormality which the writer has always found in association with the retinal symptoms which he has considered, is some disturbance in the elimination. In a large majority of cases this is evidenced on urinary examination by a diminution in the elimination of urea.

The Life Cycle of Amœba Coli in the Human Body; a Preliminary Note.—Charles F. Craig firmly believes that vacuolization is a degenerative process in amœba coli. He has observed the following varieties of amœbæ after staining the specimens by the modified Wright's method, a detailed description of which he proposes to give in a later contribution: Small amœbæ having a deeply stained ectoplasm and dimly stained endoplasm, and a large-sized collection of chromatin, generally situated at one side of the parasite, within the endoplasm. Slightly larger amœbæ, colored in the same manner, but showing a division of the chromatin into two nearly equal portions. The chromatin in both of these forms, upon careful examination, is seen to consist of very delicate fibrils and dots, arranged in a more or less definite manner. Larger amœbæ colored in the same manner, but showing a further division of the chromatin into numerous small clumps, varying in number from six to twelve or fourteen. These clumps are arranged irregularly throughout the protoplasm (within the endoplasm) of the amœbæ, and the chromatin seems to be collected in a compact and more deeply staining mass. Amœbæ of the same size, showing apparently the same number of chromatin collections, but the chromatin surrounded by an unstained interval in the endoplasm of the amœbæ and arranged somewhat regularly. The chromatin collections are smaller, more compact, and stain very deeply, are oval in form, and are of exactly the same size. The only step in the evolution of these organisms which has been missed—as shown in the stained specimens—is the actual rupturing of the amœbæ and the setting free of the spores. The writer has never seen any red blood cells within the sporulating amœbæ. It is probable that before sporulation occurs any cells which have been so enclosed are thoroughly disintegrated. The writer believes that it is demonstrated that amœba coli undergoes reproduction by sporulation, and that this manner of reproduction most adequately explains the persistence of amœbic infections. If these sporulating bodies are in reality encysted this would still further explain the persistence of such infections, as encysted parasites are more resistant to injurious influences.

The Lancet, February 6, 1904.

A Case of Acute Lymphatic Leukæmia.—The patient of H. Savory was a boy of four and a half years, with foul breath, furred tongue, impetiginous sores around the mouth and a rather quick pulse. There were a few enlarged glands on the right axillas and about the right clavicle. No splenic or liver enlargement could be made out. The bones were not tender and there was no enlargement of his thymus. He was not wasted, but his skin was sallow and very rough. Œdema and albuminuria were absent. The boy grew paler and became more or less breathless. Blood examination at once cleared up the diagnosis. In spite of every remedy used, he grew steadily worse and died in six weeks.

The Physiological Action and Antidotes of Snake Venoms, with a Practical Method of Treatment of Snake Bites.—L. Rogers tabulates the effects of snake venom of various kinds on the nervous system, blood, and arteries. On the nervous system the general effect is that of respiratory and vasomotor paralysis. There is a general loss of coagulability in the blood, and the vessels are constricted. Calmette's serum receives high commendation for its antidotal properties. Adrenalin counteracts the circulatory failure due to the vasomotor paralysis. Bandaging of the limbs may also increase blood-pressure. As to the method of treatment referred to in the title, permanganate of potash is the remedy of choice. First a ligature is placed around the limb above the site of inoculation of the venom, and then a small incision is made through place of injection, into which pure crystals of the permanganate are rubbed with a little fluid, the idea being to neutralize as much of the poison as possible before it has had time to be taken up into the circulation.

A Case of Ovarian Fibroid Tumor Removed by Posterior Colpotomy; Subsequent Pregnancy.—J. Phillips reports the case of a woman of twenty-eight years, married one year and considering herself at the fourth month of pregnancy. Amenorrhœa, morning vomiting, and mammary distension were all present. She was suddenly seized with a violent pain in the right iliac region and was obliged to take to her bed. There was no hemorrhage. Examination showed a fixed swelling of the size of the closed fist blocking the upper third of the pelvis. The uterus, showing all the physical signs of a four months' gestation, was pushed upward and forward by the growth, which was apparently attached to the lower and posterior segment. The conjugate diameter of the pelvic inlet was reduced to a size just sufficient to pass two fingers by the obstruction. Under an anæsthetic an attempt was made to push up the growth above the brim, but this failed, and as the patient declined to submit to a Cæsarean section, induction of abortion was performed and the uterus was empty. Three weeks subsequently the growth was found to be somewhat smaller in size, fixed and attached to the lower uterine segment. A diagnosis was made of subserous fibroid tumor, and it was decided to attempt its enucleation by a vaginal operation. The cervix was pulled downward and forward by means of a vulsella. A transverse incision was then made into Douglas' pouch and several spouting vessels were secured. On incising the peritoneum about a tablespoonful of clear fluid escaped; on inserting the finger the tumor was felt closely attached to the posterior and right wall of the uterus, and the posterior portion of Douglas' pouch. The adhesions were gradually broken down and a lump of creamy white color was freed; a vulsella was attached to the lower portion, and it was delivered slowly through the vaginal opening. The tumor was found to be attached by a pedicle consisting of right broad ligament and Fallopian tube to the right uterine cornu. This pedicle was ligatured and the mass was cut away. The edges of the vaginal wound were brought together, and a small gauze drain was inserted into the peritoneal cavity. Convalescence was quite uneventful. A few months later the patient became pregnant and was delivered easily and naturally of a full-time child. The puerperium was normal in every way. She has since remained quite well.

The Lancet, February 13, 1904.

An Unusual Case of Salicylic Acid Poisoning.—The patient of J. K. Matheson was a boy suffering from erythema iris over nearly the whole body. Starch poultices had been applied to remove all the scabs, and then Lassar's paste, which contains salicylic acid, was applied locally and the iodide given internally. This treatment caused marked improvement, but seventeen days later the boy began to complain of headache, sore throat, slight fever, insomnia, light delirium, and complaint of noises in the ear. Later the fever became quite high and the

pulse weak and irregular. Cessation of the applications and the moderate use of stimulants removed all symptoms.

Coma, Apparently Due to Distention of the Bladder.—R. Main was called to see a man of middle age, whom he found unconscious with facial twitching, livid face, absence of lid reflex, and stertorous breathing. The condition suggested uræmic coma to the author. Urine previously passed was examined but showed nothing abnormal. A distended bladder was found and by catheter a large quantity of blood and urine was drawn off. In about twelve hours the patient recovered consciousness. The patient was thereafter in apparently good health but unable to micturate, though stricture and prostatic enlargement were wanting. Later uranalysis was negative except as to an excess of acidity.

Etiology and Treatment of Suppuration of the Labyrinth.—W. Milligan enumerates as the most frequent causes of infection of the middle ear: (1) Suppuration of the middle ear extending through the external labyrinthine wall; (2) suppuration originating at the base of the brain and running along the perivascular or perineural sheaths of the auditory of facial nerves; (3) blood infection, and (4) injuries. He enumerates the following points as guides to operation: (1) In any case of suppurative middle-ear disease when well-marked nerve deafness upon the affected side is accompanied by frequent attacks of vertigo and nausea and by nystagmus, either constant or intermittent, a careful search should be made for the presence of any fistulous tract leading into the labyrinth. If found, such tract should be opened up and explored; if not found, however, an exploratory opening through the horizontal semicircular canal or foot plate of stapes is justifiable. (2) In all cases of suspected labyrinthine disease of septic origin the vestibule should be promptly opened. (3) In cases of chronic suppurative middle-ear disease accompanied by the presence of cholesteatoma and erosion of the external labyrinthine wall free opening of the area of involvement should be effected. (4) In cases of suspected cerebellar abscesses, accompanied by symptoms indicative of labyrinthine involvement, the operative pathway should be *via* the middle and internal ear to the posterior surface of the pars petrosa—in other words, through the median wall of the mastoid antrum. In this way the labyrinth is opened up, the anterior portion of the corresponding cerebellar lobe is exposed, and any extradural abscess lying upon the posterior surface of the pars petrosa would at the same time be located and drained.

The Significance of the Zoological Distribution, the Nature of the Mitoses, and the Transmissibility of Cancer.—The interesting paper of E. F. Bashford and J. A. Murray can be reviewed here only in outline. They find that new growths in the common domestic animals are far more common than has been generally supposed and note that the great diversity in the habitat, food, and conditions of life generally of the forms in which malignant new growths occur relegates such external conditions to a subsidiary rôle in determining the incidence of the disease, and shows that the essential factors must be sought in the potentialities which reside in the cells constituting the living organism. The progressive increase in the size of malignant tumors has been found to be due to the division and increase in the size of their constituent cells. Mitotic division of the nuclei generally precedes division of the protoplasm. A complicated sequence of cell-changes has been found to be characteristic of carcinoma and sarcoma alike. This sequence is the same as that which initiates the origin of the sexual generation in plants from the asexual, and is terminal in the history of the sexual cells in animals. It must be noted also that all the cells of the malignant new growths do not undergo the reducing division, a certain number differentiate in the direction of the tissue among which they have arisen, and in the secondary growths when present somatic mitoses occur in the growing margin, which is also a feature in the growth of cancer when transferred to a new host. The transmission of cancer from man to animals or from one animal to another of different species has never been accomplished, but transmission from one animal to another of the same kind is easy. The authors find that while in mice, many of the transmitted portions degenerate, a few remain of normal appearance and gradually increase in number. But in such experiments the malignant material does not produce metastases naturally, and its malignancy is only evidenced by its progressive growth and the undifferentiated character of the cells. The process is in no sense an infection, the tissues of the host not participating in the formation of the new parenchyma.

British Medical Journal, February 6, 1904.

Note on the Nature of the Parasitic Bodies Found in Tropical Splenomegaly.—W. B. Leishman points out the close resemblance of the parasitic bodies found in tropical splenomegaly to some bodies recently described by Wright and found by him in a patient suffering from Delhi sore. Wright found in the cells of the tissue—removed by curetting the ulcer—large numbers of small parasitic bodies which are very closely analogous with the parasites of tropical splenomegaly. Ross has often found in the pus of Delhi sores large numbers of a flagellated organism, the Cercomanas hommis. It is just possible that Wright's parasites may prove to be altered cercomonads. As to the nature of the spleen parasites, the writer believes that these bodies represent an involuted stage of a flagellate organism. The failure in all cases to detect the parasites in the peripheral blood is a strong argument against their being intracorpuscular.

Notes on an Ineffectual Treatment of Cancer; Being a Record of Three Cases Injected with Schmidt's Serum.—D'Arcy Power states that there is no doubt that a reaction takes place after the injection of Schmidt's serum. The temperature rises and with it the pulse, but the respirations, as a rule, are not affected. This rise of temperature is not peculiar, for it follows the injection of serum, which admittedly contains toxins, and in all probability any similar serum would produce a similar result if it were active. It cannot be accurately said that the reaction is specific. In the history of one case reported by the writer, the most typical reaction took place, while subsequent examination of the patient's tissues failed to detect any malignant disease. Although the local effect on the tumors was apparent from the inflammation which developed as a result of the injection, still the writer was not satisfied that the serum acted by selection upon malignant tissues only. He thinks it intensified any preëxisting inflammation. The treatment is painful apart from the succession of hypodermic injections. Malignant disease progresses, even to a fatal issue, while the injections are being given. The writer concludes that, as far as his experience goes, the method is of no service, but it may be fairly argued that the trial he has given it is insufficient, and that further observations are desirable.

Some Practical Points Associated with Appendicitis.—W. D. Spanton writes that the more he sees of appendicitis the more is he convinced that it is far safer to operate too soon than to defer it a minute too long. He admits that it is the graver cases mostly that come under his observation. Still, he believes, that even when it is deemed wise to wait in hope, it too often develops that sudden symptoms of the worst character arise while the physician is hoping for the best. There is a certain proportion of patients that will get well with ordinary care and treatment, especially strict recumbency. But in all cases of doubt it is far safer for the patient and more to the credit of surgery, to act soon, and make practically certain of saving the patient's life. The nature of the operation can be decided only after it is begun. The appendix should always be removed when it can be done with safety. This is sometimes impossible, and the condition of the patient often requires as rapid and simple a procedure as can be. In all instances free drainage may prevent imminent death, and prove the first step toward complete recovery, even when it is not possible to do more. No one ought to be allowed to die unopened, unless actually moribund. Some most desperate cases do get well. The author gives a brief history of a number of cases. He has seen several cases in which the pain was so slight as to be hardly mentioned by the patient. The locality of the pain is very misleading. Epigastric pain is almost invariably associated with peritonitis. It is not uncommon for the appendix and ovary to be adherent. Appendicitis occurs comparatively frequently in young women at the catamenial periods. Abdominal tension, especially with rigidity of the right abdominal muscles almost always devotes formation of pus or circumscribed peritonitis. Many cases with localized swelling without very marked constitutional symptoms recover without operation. There may be no swelling, and still the appendix may be gangrenous. Temperature counts for little except when a sudden rise indicates grave mischief. Localized painful swelling, with steady rise and fall of temperature, denotes pus, and ought to be evacuated before bursting into the general cavity. Each case is one unto itself and must be considered on its own merits.

British Medical Journal, February 13, 1904.

The Treatment of Myiasis.—G. H. Younge says in relation to the treatment of myiasis that the larvæ can be at once gotten rid of by the following method: The tip of an ordinary probe is lightly smeared with vaselin and pressed on to a little calomel, so as to take up about 1 grain of it. It is then passed into the cavity containing the larvæ and gently moved round it. The calomel kills the larvæ in a few minutes. They can then be removed by gentle pressure or by syringing the cavity with a little

rm boracic lotion. The drug seems to destroy or neutralize the excretory products of the larvæ, which often cite considerable local inflammation and high fever. is fatal to most of the lower forms of life.

A Case of Vesicular Mole of Unusual Size.—Thomas ter Jones describes this case. The patient was aged ty-eight years and had had eight children. Five years ore she passed a similar mole but much smaller. hen the writer was called to see her, she was having ng labor pains. No fœtus could be felt. Masses the cysts presented themselves at the os. The patient s put under chloroform, and the writer introduced his d into the uterus and got the whole mass of cysts y without much difficulty. He kept his hand well r the uterus and injected ergotin hypodermically l hemorrhage did not occur. The patient made an unntful recovery. The mass weighed five pounds four ces. The cysts looked somewhat like grapes, and tained a gelatinous material, slightly tinged with red.

ome Deceptive Abdominal Conditions and the Question Operation.—A. H. Tubby calls attention first to the dition of the pulse and temperature. He says that the ditions of gravity are two: First, a normal temperature h a pulse-rate of 100 or over; secondly, a more serious dition, a subnormal temperature with a rising pulse. the abnormal ratio has been established for a day or ger, the prospects of surgical interference are exmely unfavorable, because the altered ratio is signint of the absorption of septic products. It is important only to ascertain the number of leucocytes but the o of polymorphonuclear cells. If these are increased n the normal rate of 65 per cent. to over 70–75 per t, then pus formation is certainly present. Rigidity symptom to be carefully watched, particularly if it be sistent. Vomiting is a very variable sign. Distention is n absent in the early stages, but in the later stages of dominal disease the fatal significance is only too well wn. Diarrhœa occurring in the course of acute appdicitis is generally significant of septic absorption n a non-evacuated abscess. Local tenderness is alys of value as a guiding point to the site of the lesion. persistence of hæmatemesis and melæna after an injury n association with a suspected gastric or duodenal r, may be such as to determine the question of operaor otherwise. The presence or absence of increasing dominal dulness is an important factor in doubtful es of injury when it may be that a solid viscus has n ruptured, and blood is being poured out into the itoneal cavity, or the dulness may be due to effusion pus or fluid, or to matted intestine with adhesion, as appendicitis. Effusion of blood beneath the abminal walls is not a symptom to be relied upon and uld be considered only with other symptoms. The ociation of pleurisy and perigastric abscess is well wn, so also is the existence of subdiaphragmatic cess secondary to appendicitis, and the presence of d at the right base. As to the chest symptoms, point lies in their persistence preceded by a history bdominal trouble.

Berliner klinische Wochenschrift, February 1, 1904.

timulating the Secretion in Nursing Women.—Zlocisti nts out the necessity of encouraging nursing instead of ttle-feeding and reports the results he has had with a rified form of cotton seed used as a galactagogue. The ervations of dairymen have established the value of oil cake obtained as a by-product in the expression of oil from cotton seed as a means of increasing the milk put of dairies and the author has employed a purified duct deprived of its indigestible cellulose constituents a similar purpose with nursing women. The results wed that the preparation was not found disagreeable take by the women and that it did not seem to cause undesirable effects. In all of the twelve cases in which as given it seemed to cause a very marked stimulation the milk flow, which became apparent on the third or rth day, when twenty-five to thirty gm. of the substance d been administered.

Cytodiagnosis of the Cerebrospinal Fluid.—Meyer abstracts the observations of the French school who have developed this method of diagnosis and appends the results of his own investigations. In thirty-five cases examined, lymphocytosis was found fourteen times, which comprised eleven cases of undoubted general paralysis and three in which the same diagnosis was probable. In four cases, viz., of paralysis, of chronic alcoholism suspected of paralysis, of multiple sclerosis and of katatonia an increase of small mononuclear leucocytes was observed. In the other seventeen cases, mostly functional in nature, but including one case of paralysis, no lymphocytosis was observed. These results are in harmony with those of the French authors, and show that in nearly all cases in which a condition of chronic meningeal irritation could be assumed, lymphocytosis of the cerebrospinal fluid is found. When this is present an organic lesion probably exists, and therefore the point may be of importance in differentiating functional and organic states. What the value of such examinations is in the differential diagnosis of various organic conditions remains to be seen.

Münchener medizinische Wochenschrift, January 26, 1904.

Severe Discoloration of the Skin Following the Injection of Adrenalin.—Schücking has used his preparation with good results in plastic operations on the vagina, but believes it increases the postoperative nausea. In one case after 1¾ c.c. of a 1–100 solution had been injected the patient's skin acquired a deep bluish black color resembling that of Addison's disease and lasting one-half hour. The pulse remained palpable, but respiration became shallow until artificial respiration was used.

A Rapid Gasometric Method for Determining the Sugar in Urine.—Riegler has devised a simple yet accurate method for determining the amount of glucose in diabetic urine which possesses the advantage of taking very little time. It depends on the decomposition of potassium permanganate by glucose into CO_2 and potassium carbonate. The amount of the latter is estimated by adding dilute sulphuric acid, and measuring the CO_2 gas given off. On consulting a table the amount of glucose required to produce a corresponding amount of potassium carbonate is obtained, and the results are said to be more accurate than with the usual methods. A detailed description of the apparatus, working directions, correction tables, etc., is given.

An Improved Azotometer for the Quantitative Determination of the Urea and Uric Acid in Urine.—Jolles has simplified the apparatus used in his method for determining urea and uric acid, and describes its perfected form. The method for urea consists in diluting the urine and adding phosphotungstic acid. A measured amount of this mixture is treated with sodium hypobromite solution in the apparatus, and the amount of liberated nitrogen read off. The same apparatus is used for the uric-acid determination. The urine is mixed with ammonium acetate and ammonia. The precipitate is washed with ammonium carbonate and boiled with magnesia to drive off all ammonia. The result is acidified and oxydized with potassium permanganate. The fluid is then alkalized with sodium hydrate and decomposed with hypobromite solution in the apparatus. The amount of nitrogen corresponds to a uric acid content obtained by consulting a table.

The Origin of the Basophilic Granular Red Blood Cells.—Naegeli reviews the arguments of those observers who consider these granules as degenerative, and of those who take the opposite view and hold that they are the result of response to a stimulus and are therefore regenerative in nature. Under the author's direction Lutoslawski made a series of observations in animals poisoned with lead. These corroborate the conclusions of Sabraze's, who found that acute poisoning fails to produce the granules, that if they have been formed as a result of chronic poisoning, a large increase in the dose of the lead causes them to disappear, and also that they disappear before death. This looks as if they were formed as regenerative bodies, but the author does not consider the question settled, though he says that it seems certain they cannot be degenerations. Whether they are the result of changes in the nucleus or in the cytoplasm is also still undecided.

The Acute and Chronic Circumscribed Inflammations of the Colon.—Bittorf describes five cases in which, after a greater or less degree of constipation, a tender abdominal mass developed, usually in the region of the sigmoid, and there was an accompanying rise of temperature. One of the cases was remarkable for the development of a large exudative mass in the left iliac region, while under observation, together with a leucocyte count of 24,000. The mass was absorbed in about eight days and recovery followed. Castor oil was found the most efficient purgative in all the cases. Such conditions begin through the gradual accumulation of fecal particles in the haustra of the intestine. As the collections increase in size they become dry and irritating to the mucous membrane, so that by degrees the submucosa and peritoneum become inflamed and the clinical picture of the condition is produced. In the chronic cases there are moderate temperature, constipation, loss of appetite, malaise, nervous disturbances, and sometimes diffuse pains in the left iliac region, together with a sausage-shaped mass in the same situation. The treatment comprises laxatives, compresses to the abdomen, diet, rest in bed, and massage.

Book Reviews.

ASTHMA IN RELATION TO THE NOSE, with Notes of 402 Cases. By ALEXANDER FRANCIS, M.B., B.C. Cantab. London: Adlard & Son, 1903.

THE author regards the ordinary classification of asthma as untenable and misleading. For him it is due to spasm of the bronchial muscles probably always induced by reflex action and not due to any mechanical obstruction of the air passages. The nose comparatively rarely supplies the immediate exciting cause of the asthmatic reflex, but in the asthmatic state a morbid connection exists between some parts of the nasal apparatus and the respiratory center whereby the stability of the latter is affected. In other words, some part of the nasal mucosa has a controlling influence on the respiratory center and that area is on the septum. He employs the usual measures of treatment, but his procedure *par excellence* is to cauterize the septum with the galvanocautery point from a spot opposite the middle turbinate forward and slightly downward. The results he brings forward are remarkable. We can only say that the same method in the hands of others has not been by any means so successful.

A COMPEND OF PATHOLOGY, GENERAL AND SPECIAL. A Student's Manual in One Volume. By ALFRED EDWARD THAYER, M.D., Professor of Pathology, University of Texas. Second Edition, containing 131 Illustrations. Philadelphia: P. Blakiston's Sons & Co., 1903.

THE domain of pathology has received such important additions through the recent investigations in the fields of hemology, bacteriology, parasitology, etc., that constant changes are necessary to keep the textbooks representative of the present status of the science, while the subject of immunity has made such great advances that most of the older views as to the nature of disease have undergone important modifications.

The present volume is thoroughly modern in its treatment of all of these topics and should be of interest to all who are anxious to follow the trend of thought which is molding the pathology of to-day. Most of the important recent contributions have been incorporated and the tabular arrangement adopted by the author in many instances, is most valuable in illustrating the philosophy of the various branches of the subject. The illustrations are excellent and, together with the admirable mechanical execution of the volume, combine to make it a most attractive handbook.

TECHNIK UND DIAGNOSTIK AM SEKTIONSTISCH. Von Dr. RICHARD GRAUPNER, Assistenzarzt am Kinderkrankenhaus und Dr. FELIX ZIMMERMANN, Früher Volontärassistent am Pathologischen Institut der Universität zu Leipzig. Mit 126 Abbildungen in Dreifarbendruck auf 65 Tafeln und 25 Abbildungen im Text. Zweiter Band. Zwickau, Sa.: Förster und Borries, 1899.

As the title indicates, this is primarily intended as a guide for practical work and to assist the inexperienced or occasional performer of autopsies in making a correct diagnosis. The tone of the book is therefore much less philosophical than is usually the case with German productions, and it is well adapted to compensate for lack of practical training in this difficult subject. The chief interest naturally attaches to the plates, which are exquisite examples of what can be done by the three-color process, and show a clearness of detail and fidelity to natural coloring rarely attained. The value of the pictures is greatly enhanced by the fact that the originals are the actual handiwork of the authors themselves, and therefore have been painted with a discrimination impossible to the lay artist. All but three of them were done directly from the fresh specimens, special care being taken to catch the proper color shades before these should have become altered by the rapidly oxidizing effect of exposure to the air. The important features of each case are concisely presented in appended paragraphs of description. In the volume of text the entire field of gross pathology is clearly discussed from the purely practical standpoint, and many helpful tables of conditions occurring in each organ are given. The work is surpassed by few in beauty or in usefulness.

A TEXTBOOK OF LEGAL MEDICINE AND TOXICOLOGY. Edited by FREDERICK PETERSON, M.D., Chief of Clinic, Nervous Department of the College of Physicians and Surgeons, New York; and WALTER S. HAINES, M.D., Professor of Chemistry, Pharmacy, and Toxicology, Rush Medical College, in affiliation with the University of Chicago. Vol. II. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

WITH the second and last volume of this work is included a leaflet with evident suggestions for the reviewer, which end as follows: "In fact, the entire work is overflowing with matters of the utmost importance, and expresses clearly, concisely, and accurately the very latest opinions on all branches of forensic medicine and toxicology." In spite of this optimistic statement we regret that we cannot alter our views expressed after reading the first volume when it appeared, for we find little here that has not been said before in a better way; and a great deal has been omitted. It was hoped that a textbook with these pretensions would naturally contain much fresh matter and be clearly a new departure, but to our disappointment we find that the bulk of the book is modelled upon trite and oft-repeated lines, and we fail to find among the names of the contributors more than two or three who have taken even a prominent place in their profession. We are sorry to find that the medicolegal consideration of insanity has received such scant notice, for beyond the purely clerical reproduction of the laws of the various States, which are likely as not to be modified at the next meeting of the various legislatures, there are but four or five pages devoted to the consideration of the powers and duties of committees of incompetent persons, and nothing is said about civil or criminal responsibility. The articles of most value are those which have done duty before in Witthaus' or Hamilton's treatises, and beyond slight modifications or additions, such as the blood-serum tests in Dr. Wood's contribution, are practically the same as when they appeared in their virgin state, and even a superficial comparison will show this. In this connection it is inconceivable how men with a reputation and position of those who have erred in this way, could offer practically the same literary material to two publishers. Certainly the editors themselves have shown a lamentable carelessness in not securing original articles.

The make-up of the work is good and eight of Hoffman's vividly colored plates that were not used in the first volume are utilized in that before us.

THE TENEMENT-HOUSE PROBLEM, Including the Report of the New York State Tenement House Commission of 1900. By various writers. Edited by ROBERT W. DE FOREST and LAWRENCE VEILLER. Vol. I and II. New York and London: The Macmillan Co.

THIS work very satisfactorily fulfils its mission in discussing the various and intricate problems of tenement-house reform. No pains have been spared to obtain accurate information regarding existing conditions from expert sources, and the result is a mass of statistical data that cannot fail to appeal to the social economist and the sanitarian. In no other city can overcrowding be studied to better advantage than in some of the lower and east-side districts, where the tenement population is more dense than in any similar locality in the world. The numbers that are thus massed are truly appalling. Nor can the causes for this be easily obviated. Manhattan Island, long and narrow as it is, has very few facilities for expansion. The poor to be near their work must be necessarily massed in accessible quarters. With high taxation space becomes necessarily limited, and property holders, to realize upon their investments, are forced to multiply living rooms in every conceivable way. The room that cannot be gained on the ground is obtained by piling up structures to increase their height. Backyards are sacrificed, light and air excluded, and the diseases of poverty multiply in proportion. All these conditions are graphically described in this admirable report of the commission. The truth of the adage that one-half of the world is ignorant as to how the other half lives is strikingly shown by the flash-light pictures of the dark, unventilated, and foul rooms of many of the populous tenements. Even the air-shafts are receptacles of filth, the fire-escapes encumbered with litter, and the inner watercloset uncleanly beyond description. These are the object lessons that must force conviction on the most apathetic observer. How to remedy this deplorable state of affairs is the burden of the argument of the different writers. Whether we view it from the moral, social, or sanitary standpoint, the necessity for radical reform is apparent. Every human quality is tainted in such an atmosphere. Hence it is not surprising to learn that moral instincts become suppressed, that vice thrives, that temperance increases, and, last of all, death from preventable disease balances the unequal struggle for existence. The commission has done very commendable work in mitigating many of the present evils, but it is merely a commencement in reform rather than a consummation of even reasonable expectations. The problem is tackled from the right quarter by educating the poor as to their rights and privileges, at the same time by force of law compelling the owners of tenements to respect ordinary sanitary regulations. Each contributor has done his part in such direction, especially those who have treated of the dangers of tuberculosis and other diseases from overcrowding. As a contribution to the cause of municipal reform this book is a notable and enduring monument to the conscientious and painstaking efforts of its contributors.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 8, 1904.

ROBERT T. MORRIS, M.D., CHAIRMAN.

Facio-hypoglossal Nerve Anastomosis.—Dr. A. S. TAYLOR presented two cases of this kind. (See page 321).

Dr. ROBERT F. WEIR said that Cushing had been the first in this country to undertake this operation, the spinal accessory nerve being used in his cases. While there was improvement, it was associated with conjoined synchronous motions of the trapexius. This was quite a serious objection, and hence, the hypoglossal nerve was substituted. Personally, he did not expect the same success from grafting into the hypoglossal as when the spinal accessory was used, because the one did not secure an end-to-end anastomosis and could not expect so much nerve regeneration. He had tried the method in his ward upon a woman who had developed facial paralysis after a mastoid operation. Because of the long duration of the palsy it was not to be expected that the operation would be followed by as much success as in the more recent palsies. He had found the technique very satisfactory, and the operation had been followed by primary union. It was too soon, of course, to speak of the result.

Dr. H. LILIENTHAL thought one should be pretty sure that spontaneous recovery might not take place before resorting to this operation of nerve anastomosis. He knew of at least one case in which, after rheumatic paralysis, recovery took place after an interval of a number of months. If he remembered correctly, Cushing's case was of considerable duration. He was of the opinion that even associated shoulder movements were to be preferred to a possible permanent derangement of the tongue.

Dr. THOMAS H. MANLEY entirely agreed with the last speaker as to the possibility of spontaneous regeneration of the nerve. He recalled one case in which this occurred even after ten months. It was well known that there was no other tissue in the body which possessed the regenerative activity of nerves. In one of the reported cases a certain degree of wry neck followed the operation.

Dr. C. A. ELSBERG referred to two cases coming under his observation. The first occurred in a man who had had rheumatic paralysis of eight months' standing. The paralysis had not been benefited at all by persistent treatment in the out-patient department. He was kept under observation, however, for a considerable time, and when heard from a few months later, no operation was necessary. The second case occurred in the Montefiore Hospital, and when seen there was a palsy of about eight months' standing. In that case, after one or two months, improvement began, and it was now proceeding quite rapidly. If these cases had been operated on quite soon they would have probably yielded very good results, but it could not be said that the recovery was due to the operation. He had searched the literature, and had found that some of these cases recovered spontaneously after from eight to twelve months. The operation described by Dr. Taylor was certainly a beautiful and attractive one, and the improvement had taken place rather more quickly than in most of those reported.

Dr. FRED KAMMERER thought a distinction should be made between rheumatic cases and those in which the paralysis was caused by a loss of nerve substance.

Dr. A. S. Taylor said that of course the question of spontaneous recovery must always be considered. In so-called Bell's palsy such recovery was the rule, but sometimes in chronic cases there were contractures of the muscles which were even more disfiguring than the paralysis. In his second case, that of the woman, treatment had been carried on for three months by the neurologist, and there had been not only no improvement, but a tendency toward contracture had developed—at least this was the opinion of the neurologist who worked with him. The question of derangement of the tongue should be borne in mind, but with proper technique there would be no unnecessary disturbance, and the derangement of the muscles of the tongue would probably be slight and temporary. This was rather a matter of faulty technique than a defect inherent in the operation itself. As Dr. Kammerer had well said, the traumatic cases, in which there was a loss of substance of the nerve, afforded almost no chance for regeneration of the nerve. The greater the length of time from an infectious paralysis to the time of surgical intervention, the less the chance of obtaining a good functional result from nerve anastomosis.

A New Procedure in Rhinoplasty.—Dr. CARL BECK presented this case that it might be judged of before the final result. Some years ago a rhinoplasty had been done on the patient by a well-known surgeon, but the result of that operation had been destroyed subsequently by an extension of the process for which the operation had been done, *i.e.* epithelioma. When the case came under Dr. Beck's care he could find no tissue on the face for an operation, and, hence, adopted the plan of taking it from the arm. The result of this operation was good, but a recurrence of the disease caused a destruction of nearly half of the nose. He had then resorted to what he believed to be a novel procedure. A large triangular flap was taken from the lower lip. This was partially separated a week after the operation to shorten the patient's sufferings, and the remaining portion of the pedicle was separated only five days ago. One advantage of using the lower lip for this flap was that mucous membrane was thus obtained. Another advantage was the thickness of the flap. He would have employed the *x*-ray treatment were it not for the shrinkage of the tissues which would have resulted, and which would have interfered with the operative procedures. *X*-ray treatment would be employed as soon as practicable after the operation.

Fecal Fistula Following Appendicitis.—Dr. A. ERNEST GALLANT presented this patient, a little colored girl. He said that fistula of the small intestine in conjunction with appendicitis he had not met with before. He had first closed the opening of the fistula, and then dissected out the scar. In doing this, the fistula was cut through a second time, and such a large gap was made that it became necessary to resect the bowel. The result was entirely satisfactory, there being primary union and a total absence of pain. The bowels moved without any medicine on the sixth day, and the child was out of bed on the tent day.

Dr. MANLEY asked whether the perforation of the small intestine was due to trauma at the first operation, or to some disease, such as tuberculosis. He would also like to know whether the union was made by means of button or suture.

Dr. GALLANT replied that from the history he understood that the original operation wound had been drained, but further than this he knew nothing about it. His closure of the opening had been by means of an end-to-end anastomosis with the Lembert suture.

Gunshot Wound of the Abdomen.—Dr. J. J. HIGGINS presented this case, and reported another. The case reported was that of an Italian who had a bullet wound midway between the umbilicus and the pubes. The operation was done five hours after the shooting. There was one opening into the jejunum, and there were seven holes some distance lower down in a space of about six inches. This portion of bowel was excised, and an end-to-end anastomosis done. Recovery took place without further incident. A week later the second patient came into Fordham Hospital with the same injury, but he absolutely refused operation. For five days there were vomiting and hiccough, the pulse and respirations were rapid, and the temperature varied between 101.2° and 103°F. During this time he was very ill, but on the fifth day his stomach was washed out and from that time on recovery was rapid.

The bullet was not located, and no blood was passed per rectum or vomited.

Retroduodenal Choledochotomy for Impacted Calculi in the Retroduodenal Portion of the Choledochus.—Dr. A. A. BERG reported this case and presented the patient. The woman had been admitted to the surgical service of Dr. Gerster in the Mount Sinai Hospital last July. She had been jaundiced for eight months, and gave a straightforward history of repeated attacks of biliary colic for some time. She was emaciated, and had had chills and rises of temperature on several occasions. A diagnosis of cholelithiasis was made, and an operation undertaken. Upon exposing the biliary apparatus, the gall-bladder was found free from calculi, but reaching from both branches of the hepatic duct through the main hepatic duct down through the common bile duct to the papilla in the duodenum was a continuous chain of calculi, varying in size from a marble to a split pea. The cystic duct was empty. It seemed to be a primary formation of calculi in the hepatic ducts, and on subsequent exploration of the hepatic ducts in the liver he was able to deliver about half a dozen stones from the ramifications of the main hepatic duct in the liver itself. The common bile duct was first opened and the stones accessible through the incision were easily removed. One stone was very firmly impacted just above the papilla, and could not be dislodged by a sharp spoon passed through the incision or by manipulation through the duodenum. Last May, in a paper on cholelithiasis, the speaker said, he had proposed a procedure recommended by Kocher for gastroduodenostomy, *i.e.* the reflection of the descending portion of the duodenum and rotation of this portion upon the longitudinal axis, turning the duodenum to the left, and exposing the common bile duct on the posterior surface of the duodenum. In this way the common bile duct became accessible in that portion which had always been a bugbear to the surgeon. In this case the common bile duct did not pass through the head of the pancreas, but even when it did so it could be easily shelled out. The advantage of this procedure was that the duodenum was not opened. The mere opening of the healthy duodenum with a healthy peritoneum was not very serious, but it was entirely different with a diseased duodenum. Dr. Lilienthal had antedated the speaker in the actual performance of this operation. It had been recently stated that this procedure was an old one, but on looking up the literature it was found that in no previous case had it been the intention primarily of the operator to do the operation which he recommended. Where there were numerous adhesions around the second portion of the duodenum this procedure was easily done. The woman upon whom he had done this operation was now pregnant, but there was no hernia present.

Dr. LILIENTHAL said that he did not do the operation as described by Dr. Berg, but opened the peritoneum, introduced the finger, and rotated the descending portion of the duodenum so that the stone presented through the peritoneum to the inner side; he had not thrown the gut over and taken the stone out from behind. He thought, however, that Dr. Berg's method was a good one.

Dr. JOSEPH A. BLAKE said that it was quite difficult to remove stones from this portion of the gut, and this seemed to him to be a good method if it could be carried out without infecting the retroperitoneal tissues.

Dr. KAMMERER said that theoretically this method of reaching the common bile duct ought to be good; he had reached the duct in this way twice this winter.

Dr. W. S. BICKHAM said that he had seen a pathological specimen in which the calculus had passed down the common bile duct to the duodenum. It had then ulcerated its way safely through the duodenum, had passed down several inches, and after the lapse of a considerable time had caused the death of the person. This was a rather remarkable circumstance when it was considered that the stone had passed safely through the narrow duct, and had finally, by reason of its unusual size, caused obstruction of the larger duodenum.

Dr. BERG said that no doubt this procedure had been resorted to many times, but it had not been previously described as a typical procedure. An interesting feature of his case was that there was a primary formation of stones in the hepatic ducts.

Some Surgical Features of Typhoid Perforation, with a Report of Four Cases.—Dr. CHARLES A. ELSBERG read this paper. The patients had been operated on by him on the surgical service of Dr. Lilienthal at the Mount Sinai Hospital. He had also observed eleven other patients operated on by others at the same hospital. He said that the operative treatment was indicated in every sense of typhoid perforation of the bowel as soon as the diagnosis had been made. Operative interference for suspicious symptoms was a course which had been declared justifiable by a number of writers on this subject. However, delay was advisable in some cases. There was still no unanimity of opinion as to what constituted the symptoms of perforation. The only symptoms of perforation *per se* to be conceived of were sudden abdominal pain and the presence of free gas in the abdominal cavity. Sudden abdominal pain was evidently not a distinctive symptom, and although the presence of free gas was almost pathognomonic, if demonstrable, this was not always possible. Moreover, all cases of perforation were not associated with the presence of free gas in the abdominal cavity.

Diagnosis.—In the cases upon which this paper was based there was usually a history of sudden abdominal pain or of increase in existing pain and tenderness. At the time when the diagnosis could be made there was more or less increase of pulse and respirations. Some of the patients had been in collapse; the abdomen had been distended and more or less rigid; at times there had been free fluid and gas in the abdominal cavity. Collapse did not occur as often as might be expected, having been present in only four out of the fifteen cases. In six of the cases the distention of the abdomen was very marked; in one case there was no distention. Diminution of the areas of liver dulness was of great assistance in making the diagnosis. This diminution was usually due to the abdominal distention. Abdominal pain and tenderness were usually most marked on the right side of the abdomen, although the entire abdomen was often tender in these cases. Free gas could only be demonstrated in five out of fourteen patients giving evidence of diminution of the area of liver dulness. In endeavoring to demonstrate the presence of free gas he had found it useful to have first the head and then the foot of the bed raised considerably while percussion was made. The temperature changes presented nothing characteristic. With regard to leucocytosis he had come to the conclusion that it had little value; its absence did not at all exclude the possibility of perforation.

Indications for Operation.—In most of the cases considered, the diagnosis of perforation of the bowel could be made almost certainly in from four to twelve hours after the occurrence of the perforation. These patients bore the operation remarkably well if the manipulations were carried out quickly. When the diagnosis was only probable, if the patient's condition were steadily growing worse it was desirable to make a small exploratory incision. If nothing were found, the operation could be completed in ten minutes, and the patient could be returned to his bed with a good expectation that his general condition would be made little, if any, worse by the operation. When the symptoms of perforation had existed for at least twelve hours and were fairly clear, the operation was justifiable. If, however, the symptoms had existed for more than twenty-four hours, and the patient's general condition was still good, and the diagnosis was yet in doubt, the surgeon was justified in advising a few hours' delay if the case could be carefully watched.

In ten of the fifteen cases the abdomen contained seropurulent fluid in considerable quantity, and there were no adhesions between the coils of intestine. In all of these cases the operation had been done in less than

twenty-four hours from the occurrence of the symptoms of perforation. In six of the fifteen cases the abdominal cavity contained free gas. Deeply ulcerated Peyer's patches could be plainly seen through the peritoneal coat of the bowel in some instances. In one case he had sewed over four such ulcers, and had desisted from sewing others because of the danger of unduly narrowing the lumen of the bowel. The patient did very well for a time, but subsequently died from the perforation of one of the ulcers that had not been sewed. Of his own four cases, three were in distinctly better condition at the close of the operation than before it. In the fatal cases death occurred in most instances from the infection of the peritoneal cavity as a result of the perforation. Typhoid perforation commonly occurred while the fever was still high. In a number of the operative cases a sudden fall of the temperature took place in the first twenty-four hours after the operation, and he had come to look upon this as of good prognostic import. The abdominal wound should be drained, otherwise it was likely to become infected. Rapidity of operating was a *sine qua non* in cases of typhoid perforation. The average duration of the operation in his own cases was a trifle over fifteen minutes. In most instances the prominent loop of bowel was found to be the one containing the perforation. When the perforation was too extensive to suture, the omentum could be sewed over the area or the affected portion of bowel anchored in the abdominal wound. When the perforation was walled off from the general cavity by adhesions it was advisable to do nothing but drain. He preferred to use general chloroform anæsthesia, preceded by a dose of morphine.

Dr. J. A. BLAKE said that the possibility of securing good results from operation had been well emphasized by the paper just presented, and he hoped the medical profession at large would not overlook this important fact. He could agree with all that had been stated in the paper. In only one case had he been able to demonstrate free gas in the peritoneal cavity. He had found three perforations in every case but one, and there was always some suspicious part requiring to be turned in. The perforations were usually closed by means of a purse-string suture, the peritoneal cavity was washed out very freely and the wound was drained so as to avoid infection. The first three cases, done in the past year, got well except the one dying on the twenty-eighth day from a relapse of typhoid fever. All of these patients had a relapse of the typhoid fever. He had also noticed a fall of temperature to the normal in the twenty-four or thirty-six hours after operation, and this had been present, he believed, in all but the fatal cases. He laid considerable stress upon rigidity of the abdominal walls as a diagnostic sign. The cases were operated upon in the hospital always less than eight hours after the perforation.

Dr. LILIENTHAL said that Dr. Blake had been very fortunate in being able to operate upon his cases so soon after perforation. Personally, he had operated upon a number of cases, and all but one had died. In a hospital a good house staff would make the diagnosis quickly, the operating surgeon could be summoned and the operation could be undertaken quite early if the necessary consent could be obtained. It was different in private practice; the diagnosis was made after much hesitation and there was still further delay before the case was seen by the surgeon. It was not surprising that under such conditions operations for typhoid perforation done in private often proved disastrous, and, as a result, the operation itself unjustly fell into disrepute. Medical men should have an understanding with the surgeons so that when a typhoid perforation was suspected there need be no unnecessary delay in securing the services of the surgeon.

The Operative Treatment Hardly Applicable to Private Practice.—Dr. A. A. BERG did not think that the exploratory operation in private practice would ever come to be a recognized procedure in typhoid-fever cases. The obliteration of liver dulness he considered a very important diagnostic sign of typhoid perforation. If there were free gas in the peritoneal cavity, there would be found on percussion a diminution along the upper margin as well as the lower margin of both the liver and spleen. The diminution of the dulness at the lower margin was not of great importance. The number of recoveries from operative interference in these cases at the Mount Sinai Hospital had not been very brilliant. One must take into consideration the type of the epidemic among other things. The older practitioners spoke of many cases of so-called peritonitis complicating typhoid fever which recovered without operation, and so long as the surgeons could only show a recovery of 30 per cent. under favorable conditions, and with operations done within a few hours after the occurrence of the perforation, the operative treatment could not be very forcibly urged upon the medical profession. Dr. Crile had shown that one of the best ways of producing shock in animals was by washing out the peritoneal cavity; hence, it was very questionable whether the washing out of the peritoneal cavity after perforation was advisable.

Free Gas Due to Another Cause.—Dr. ROBERT T. MORRIS said that he had recently operated upon a case for supposed perforation, there being much free gas in the peritoneal cavity, but had been surprised to find that the free gas was not due to perforation but to the action of the bacillus aërogenes capsulatus. Mention was made of a case that he had seen in which a patient had recovered from a typhoid perforation and had died subsequently from strangulation. If the surface were lightly scarified and two or three inches of Cargile membrane were applied to the ulcers which were on the point of perforation, he thought sufficient temporary protection would be afforded in many instances.

Dr. J. A. BLAKE said that the trouble in operating upon these cases in private was attributable not so much to the surgeon as to the physician. We should not hesitate any more to operate upon a case in private practice than upon a hospital case, and if the patient were too near to us, by reason of kinship or friendship, we should have nothing whatever to do with the treatment. One reason that he had been able to operate so early in the hospital in many cases was that he had an understanding with the medical house staff, and had been promptly called by them when perforation occurred. He knew what Dr. Crile had written on the subject of washing out the peritoneal cavity, but he still felt that this procedure was valuable and persisted in employing it. His cases had done much better since he had abandoned drainage of the peritoneal cavity as much as possible.

Dr. ELSBERG closed the discussion. He said that Dr. Morris's suggestion concerning the use of Cargile membrane impressed him as both novel and useful. According to all authorities, less than 5 per cent. of all patients with typhoid perforation recovered without perforation, and the general recovery rate from operative treatment was about 20 per cent. Even with this rate there was a considerable saving of life from resort to operation.

Claudius' Catgut.—Dr. A. V. MOSCHCOWITZ read a brief paper on this subject. He said that catgut prepared by this method had been used almost exclusively at the Mount Sinai Hospital for the past seventeen months, and had stood the test exceedingly well. The bacteriological tests made by Claudius and others were sufficiently conclusive as to the sterility of this iodine catgut. It was not only aseptic, but, owing to the imbibition of iodine, was also antiseptic. It was now used at the hospital unhesitatingly in any and all operations. They had noticed a slight loss in the tensile strength, particularly with the heavier grades, but this loss was so slight as not to mar its utility. The preparation of the catgut was simplicity itself. The catgut, as it came from the dealer, was wound in a single layer upon the glass spools and was immersed

for eight days in the following solution: iodine, one part; iodide of potassium, one part; distilled water, 100 parts. The catgut was preserved sterile for an indefinite time, but lost some of its tensile strength after six months' immersion in this solution. Any unused catgut was put back into the original solution, and was used any time after half an hour. The solution should have a deep brown, almost black, color. The prepared catgut was of a brownish-black color and preserved the characteristic odor of iodine. It was perfectly smooth on the surface, was very strong, soft and pliable, and hence was easy to manipulate. Before using, it was only necessary to rinse it in sterile water. There need be no fear of toxic symptoms arising from the iodine introduced into the tissues. He had never observed any irritant action from the use of the iodine catgut even upon the skin. The only valid objection to it was that, owing to the volatility of the iodine, it was apt to corrode surgical instruments if the jar were kept in an instrument cabinet. It also stained the linen.

Dr. JOSEPH WIENER, Jr., said he had been using this catgut in the hospital, and believed the statements made regarding it were fully warranted. It possessed many points of superiority over other forms of catgut. Its chief advantages were its strength, softness, and pliability. For the introduction of a running suture, for example, it was most excellent, and if placed in water for a few minutes it would not swell. He knew of only one distinct objection to this catgut, and that was that it began to lose some of its tensile strength after a few weeks, thus making it distinctly disadvantageous in private practice. However, for hospital work it appeared to be ideal.

Dr. Moschcowitz, in closing, said that there could be no doubt that this iodine solution would kill anthrax spores, even after an exposure of only thirty-five minutes, yet it was wiser not to use the catgut, as Claudius recommended, for eight days. This catgut did not usually begin to show any brittleness until after six months; the catgut that had become brittle at the hospital sooner than this was some that he had previously experimented with by removing the fat. There was no objection to taking the catgut out of the iodine solution, and drying it, provided it was kept in a sterile container.

A New Simple Hand Arc-lamp for Phototherapy.—Dr. HENRY G. PIFFARD presented this instrument. (See page 128.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Regular Meeting, Held January 8, 1904.

DR. CHARLES STEDMAN BULL, PRESIDENT, IN THE CHAIR.

The Status of Radium.—Dr. ROBERT ABBE presented this communication. He said that aside from the universal interest that had been attracted to the subject of radium as a newy discovered element, and its particular claims upon the physicist, it possessed certain properties that had excited the attention of medical men. Ninety years ago Faraday suggested that all matter was more or less radiant, and in radium we possessed an element which represented the climax of that idea. It had also given us a new conception of the atomic theory. The atom had heretofore been regarded as a fixed quantity upon which logical theories could be based, but it had now been demonstrated that the atom itself was capable of breaking up into infinitely smaller particles. In the case of radium, this self-destruction was accompanied by the constant emission of radiant particles, which were shot into space, and it served as an illustration of what was probably going on in all living things—the natural process of life and decay.

The radiant energy of radium could be demonstrated by means of the electroscope. This consisted, essentially, of two gold leaves, which hung together when non-electrified and flew apart when electrified. When a negative discharge approached them, they fell together—instantly, if the discharge was energetic; very slowly, if the discharge was weak. By the same method the radioactivity of radium could be demonstrated and measured.

A great many objects besides radium exhibited radiant energy. The atmosphere was full of it; rain and snow, old library books, and numberless odd things possessed it in a certain degree. With many objects it was so slight that its intensity could not be measured as could that of the larger force possessed by an element such as radium. The reason that photographic plates lying on shelves in a dark room became for a few months poor and useless was that unsuspected objects have this radiant energy to a slight degree. Radium produced a very marked effect upon the electroscope and on photographic plates, and caused certain minerals to become luminous when it was brought near them.

Dr. Abbe showed a number of tubes containing radium salts which possessed various degrees of radioactivity (two of them were from the laboratory of M. Curie, 300,000 strength), and stated that the luminescence of the salts was not entirely in proportion to their strength.

The discovery of radium was very interesting. The elder Becquerel, over half a century ago, noticed that uranium, when exposed to the sunlight, had phosphorescent properties. M. Becquerel experimented with these phosphorescent uranium rays to see if they would penetrate opaque objects, as x-rays did, and found that even uranium without sunlight would affect a photo plate through black envelopes. Madame Curie undertook to discover the reason for this. She went to the fountain source of uranium, which was a mine in Bohemia, where the uranium was obtained in large quantities from pitchblende, and the residue was thrown away. Madame Curie found that this residue possessed four times the radioactivity of uranium itself. The goldleaf electroscope was the keynote of her researches. She proceeded to make a chemical analysis of the residue, and after passing it through repeated reducing processes she finally obtained a residual sulphate which had sixty times the radioactivity of uranium. From a ton of the residue of the pitchblende from which the uranium had been obtained she was able to extract only about three ounces of the mixed sulphates containing the unknown and still unnamed radiant substance, which was still further reduced by fractional crystallization, and its radioactivity gradually increased from 250 to 500, then to 1,000. then 5,000, and finally as high as 300,000. Each reduction eliminated certain inactive metals, lead, tin, iron, bismuth, etc., and by repeated use of the electroscope a pure new metal was obtained which gave new spectroscopic lines and was called radium.

This radiant energy was capable of penetrating certain opaque bodies, but to a lesser degree than the x-rays. To illustrate their comparative penetrative power, Dr. Abbe showed pictures of various objects which were radiographed through different media by means of radium and the x-rays. He also showed an instrument called the spinthariscope, by which the actual discharge of particles from an atom of radium could be witnessed as scintillations on a sulphide of zinc screen whose crystals became brightly luminous as the atoms passed through them. The rate of progression of these particles had been demonstrated by I. J. Thompson to be about 70,000 miles per second. These particles were negatively charged with electricity, and were infinitely smaller than a hydrogen atom, which had hitherto been regarded as the chemical unit.

Some interesting experiments with radium upon seeds and animals had been reported by M. Dangsz before the French Academy of Sciences. According to those experiments, certain seeds that were exposed to radium lost their power to germinate. A guinea-pig whose spine had been exposed to the rays for a few hours became paralyzed, and similar effects were observed in rabbits. It was also

demonstrated that radium introduced into the peritoneal cavity of rabbits was apparently ineffective. Dr. Abbe said he had repeated some of these experiments during the past summer, and his results were almost in accord with those obtained in France. Seeds that were exposed slightly to radium throve better than those that had not been placed under its influence, and a rabbit under whose skin in the spinal region a tube of radium was placed and left there for a month remained apparently unaffected by it. One hundred canary seeds were exposed to the influence of radium for three days; similar seeds were also exposed to ordinary sunlight and to moderately concentrated sunlight, and still others were placed under glass of different colors—blue, yellow, and red. After an exposure of three days to radium (300,000 activity), all these seeds were planted at a uniform depth in sifted earth. Ten days later it was found that the seeds that had been exposed to the yellow light had grown two and one-half inches; those to the red light, two inches, and those to the blue, one inch. Those that had been exposed to concentrated sunlight had grown an inch and one-half; those that were exposed to the radium had grown one inch, while those that were exposed to ordinary sunlight had grown ony three-quarters of an inch. These experiments were repeated several times, and showed that the different kinds of light had exerted a marked effect upon seed growth. Seeds exposed for a long time to the influence of radium lost entirely their germinating power. Young trout and pollywogs were apparently in no way influenced by a tube of radium which was placed in the bowl of water close to them, nor had it any effect on ants, although the embryo ants were killed by it. Its failure to effect the fish and pollywogs was explained by Professor Brackett upon the theory that its radioactivity was taken up by the water, and this theory would also explain its inactivity upon intraperitoneal and other deep tissues. Becqueral was the first to observe its pathological effect npon external tissues. He carried a tube of radium in his vest pocket, and a sore resulted which ran a painful course. Curie and others had also observed that the skin was very sensitive to the influence of radium. The lesion it gave rise to appeared about two weeks after exposure, and was exactly similar in its course and appearance to an *x*-ray burn. In a radium burn which he had produced on his own arm (two hours exposure—300,000 activity), Dr. Abbe said the lesion appeared about three weeks after exposure as a red spot, very tender to the touch; the tumefaction and redness disappeared in the course of four or five weeks. For three weeks it was exquisitely tender, and yet there was no open sore at any time. An exposure of five hours made an immediate and serious lesion very painful, apparently the result of a tissue necrosis, probably a coagulation necrosis, with an obstruction of the neighboring capillaries, and a resulting excitation of capillary energy.

When radium was applied to an eye in which the retinal nerves were normally active, it immediately gave rise to a sense of luminosity.

Dr. Abbe then briefly reviewed all the published cases up to date (collected from English, French, and German journals, by Dr. Truman Abbe) in which radium had been employed in disease. These were forty-two in all. eight of lepers, seven of epithelioma, twenty-one of carcinoma, three rodent ulcer, one sarcoma, one telangiectasis, one of psoriasis. Lupus of the face or hands yields uniformly and quickly, as it does to the *x*-ray influence, and ten times more quickly than to Finsen rays.

Application of the strongest radium, 300,000 activity, ought to be a half-hour seance every second or third day; weaker specimens much longer and oftener. Rodent ulcer was cured with simple scars in a very few weeks' treatment, one or two applications a week. Small sarcomatous nodules in the shin were reported cured. In cancers most were improved, and some reported in process of cure, and one of the cheek, the size of a silver dollar, entirely disappeared. The pain seemed pretty uniformly to disappear. Carcinoma of the uterus uniformly took on a retrograde change and there was improvement in all the worst phases—bleeding, discharge, and pain—but no cures were reported.

Dr. Abbe reported seven cases under radium treatment too early for final report as yet, but showing the following results: A lupus of the zygoma eight years under observation, one and a half inches by one inch wide, perfectly cured by one application or 3,000,000 strength laid upon it for an hour and a half. Epithelioma of the ear two years, resisting all medication, partially cured by radium and finished by *x*-rays in six weeks. The result maintains perfect condition after eight months. One small epithelioma a quarter-inch on the margin of the ear, cured by three applications a half hour each, the glass tube containing the radium merely laid against it. Two cases of cancer of the uterus, much ameliorated in all symptoms, with a marked loss of cancerous cachexia. Other cases of rectal carcinoma and one of giant-celled sarcoma of the jaw were under treatment with noticeable improvement, but not yet worthy of report.

In conclusion, Dr. Abbe said that the effect of the radium upon pathological growths was similar to that of the violet and the *x*-rays, but slower than the latter. Lupus was, in almost every instance, curable by the *x*-rays and also by radium. The latter possessed at least ten times the strength of the Finsen rays and its application was less troublesome. An advantage of the radium was that it could be applied to lesions to which the Finsen rays were inaccessible.

Dr. M. Allen Starr said that in French medical literature he had seen the report of three obstinate cases of tic douloureux of the middle branch of the fifth nerve that were treated with decided success with radium. The pain was relieved within an hour or two after the application, and in one instance the cure was said to be permanent.

Dr. Abbe, in reply to a question, said that in his case of lupus of the face, only the central part of the lesion was covered by the tube. The effect of the radium extended by radiation beyond the actual limits of the tube. Rubber tissue is laid upon the ulcer and does not effect the passage of radiant energy between the glass tube and the sore.

Dr. Andrew H. Smith said that last summer, while in England, he saw a lady who suffered from a rodent ulcer, about the size of a large split pea, on the side of the nose. Applications of radium were made two or three times weekly, each exposure lasting half an hour, and at the end of six weeks the lesion had entirely disappeared. He had previously had the opportunity of watching Finsen's work at Copenhagen. Finsen's patients were subjected to daily exposures of an hour to an hour and a half for weeks and months, and while the treatment generally resulted in a cure, there were a certain number of cases in which the lesions extended into the nostrils and beyond the reach of the rays. In such cases, Dr. Smith thought radium might prove a very valuable auxiliary to the violet rays.

Questions of Uranalysis Bearing upon the Diagnosis of Contracted Kidney.—Dr. Beverley Robinson read this paper (see p. 325).

Dr. Edward G. Janeway said the difficulties of diagnosis to which Dr. Robinson had referred in his paper were in some cases almost insurmountable. He recalled one instance in which a man was brought to the hospital in a comatose condition, and the diagnosis lay between uræmic coma and apoplexy. The urine contained neither albumin nor casts. The man died and the autopsy showed contracted kidneys and no evidences of apoplexy. In another case he had in mind the diagnosis of contracted kidney was considered probable; the urine was of low specific gravity, but over thirty examinations failed to reveal the presence of albumin or casts. The

autopsy showed contracted kidneys. Twenty years ago he saw a man who had been refused life insurance because of negative casts. When first examinations of morning and evening urine were made only cylindroids were found, but on getting a specimen at the same hour as insurance examination numerous myeline casts were found. Further questioning elicited the fact that this specimen was always passed after the man had engaged in a boxing bout and then cooled off with an alcohol sponge bath. Upon discontinuing his exercise, the casts immediately disappeared from the urine. He had, after twenty years, again consulted the speaker, fearing arteriosclerosis. He said that the urine had been normal, though he had failed as yet to send a sample for examination especially requested after exercise. That passed in office only contained cylindroids. The arterial pressure was not raised.

Dr. Janeway said that a study of these cases showed that a hasty conclusion should not be based upon either the presence or absence of albumin or casts. The examination of a single examination was of very little practical value; repeated examinations were necessary. In reply to a question as to whether the amount of urea excreted would not be a valuable clue, Dr. Janeway said it could not always be relied upon. Some persons apparently got along very well with a low urea output. Each case had to be studied on its own merits. Diet, exercise, occupation, etc., were all factors to be considered.

Dr. HERMANN M. BRIGGS said he recenty saw in consultation a man who had apparently enjoyed good health until recently, when he had an attack of constipation lasting four or five days, followed by nausea and vomiting and inability to take any food whatever. Then for six days he failed to pass a drop of urine, and on the seventh day he succeeded in passing two ounces. This contained a good deal of albumin and some casts. On the day Dr. Giggs saw him he had passed ten or fifteen ounces of urine; this had a specific gravity of 1020, and was free from albumin and casts. The patient was a Hebrew who had undergone considerable strain in his business, and his symptoms were for a time regarded as being of a neurotic origin. Under saline irrigation the quantity of urine increased within three days to one hundred ounces, and the patient, who was living out of town, improved so much that he came to New York. A few days later he began to have difficulty in breathing, the respirations being sighing in character. The urine was again examined, with entirely negative results. The breathing failed to improve and after a few days the man suddenly had a convulsion and died. No autopsy was obtainable, but the case was regarded as one of small kidney.

Dr. GEORGE L. PEABODY said that while a single examination of the urine might show no abnormality in many of these cases, he was firmly convinced that by repeated examinations evidences of renal changes would be discovered in substantially every instance. It was extraordinary how well some patients could bear complete anuria without showing any evidence of uræmia. The speaker said he thought too much stress was still laid by many upon the quantity of urea excreted. Taken by itself, this had no clinical significance. We were still in ignorance regarding the real cause of uræmia. The speaker said he recently saw a case in the hospital where uræmic symptoms suddenly supervened while the kidneys were apparently active. The renal symptoms coming on in the course of typhoid fever were the result of a parenchymatous rather than an interstitial inflammation, and the presence of albumin and casts in the urine of typhoid fever patients did not usually complicate either the treatment or the prognosis of that disease.

Dr. JOHN W. BRANNAN said that about three weeks ago he saw, in consultation with Dr. Bartlett, a man with an irregular and intermittent heart and evidences of arterial sclerosis. His urine had been repeatedly examined by a competent chemist, with entirely negative results. A subsequent examination showed albumin and casts in abundance, although the symptoms were no more indicative of renal complications than earlier in the disease. The patient has since died with all the symptoms of a chronic diffuse nephritis.

A Portable Sphygmomanometer.—Dr. THEODORE C. JANEWAY (by invitation) demonstrated this apparatus, which had been devised to provide a simple portable sphygmomanometer which should obviate the more serious defects of the forms obtainable at present. Of these too small width of the compressing armlet was the most serious. Von Recklinghausen had demonstrated conclusively that for arms of 24 cm. circumference a width of 10 cm. was necessary, and the majority of adult arms measured 24 to 34 cm., and required not less than a 12 cm. cuff. This width the speaker had adopted. The only original feature of the instrument was the construction of a portable U-tube manometer in a case, which measured only 10¼ by 4½ by 1½ inches, and, with armlet and Politzer bag used for inflation, weighed 2¼ pounds. The whole would go easily into any bag. The Politzer bag was adopted from Erlanger, the jointing of the manometer tube from Cook.

With this instrument only pressure tubing was used and the manometer had a caliber of 3 mm., so that estimations of diastolic pressure might be made by noting the lowest point of maximum pulsation, as well as the ordinary measurements of systolic pressure by obliteration on return of the pulse. Erlanger's and Stautrie's, the only others which did this, were bulky and costly instruments.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting, held on January 26, in celebration of the twentieth anniversary of the organization of the society, Dr. James Hendrie Lloyd read a paper entitled "The Metaphysical Conception of Insanity," in which he pointed out the impossibility of a rigid differentiation of mind and matter, and the resulting fallacy of basing any classification of insanity upon such an attempted distinction. Mind is merely a manifestation of matter, and insanity, as a disease of the mind, must involve the nerve-cells of the brain, although all may not suffer in equal degree if at all. Dr. S. Weir Mitchell presented a communication entitled "The Mental Processes by Which the Rest-treatment Was Developed." It was during the Civil War that, together with Drs. Morehouse and Keen, Dr. Mitchell was struck by the extraordinary recuperating influence of rest in soldiers prostrated by the effects of prolonged marching. Later, in 1874, while treating a woman suffering from nervous exhaustion, Dr. Mitchell again observed the beneficent effects of rest, but in this instance it became necessary to modify the procedure by some form of artificial exercise, and accordingly massage was applied for the purpose. The patient, whose ailment had resisted the efforts of many of the best men of the day, recovered and is still living and well for her years. At a still later period, electrical stimulation of the muscles was added as a part of the treatment. Though the plan of treatment was at first received with some incredulity and opposition, it has survived, and is now universally recognized as an established and beneficent therapeutic procedure. Dr. J. Chalmers Da Costa read a paper entitled "The Surgical Operations Applicable in Insanity." He did not hold out a hopeful prospect of relief from surgical measures applied to the treatment of the various forms of mental alienation, although he admitted that the existence of insanity should of itself not necessarily contraindicate operation. Of course, if the mental disorder is a direct result of a condition removable by surgical interference, this should be instituted. The rules governing the surgical treatment of the insane were

the same as those governing the surgical treatment of the same. Dr. Francis X. Dercum read a paper on "Mystic Medicine." He pointed out the reverence that mankind had always had for the mysterious, and the various forms in which, for therapeutic purposes, advantage had been taken of this peculiarity, both by physicians and by laymen. As types he mentioned mesmerism, metallotherapy, and hypnotism. With reference to the last, which he described as an artificial form of hysteria, he expressed a caution as to danger not alone to the hypnotized but also to the hypnotizer.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At a stated meeting, held February 10, Dr. Alfred Stengel presented the report of the committee appointed to consider the question of the prevention of the communication of contagious diseases, and it was adopted after protracted discussion with little modification. The report was in the nature of a series of recommendations to the Philadelphia Department of Public Health and Charities, which covered the following matters: Making it obligatory upon heads of households to notify the Board of Health of the existence of cases of contagious diseases and to disinfect the premises on recovery, removal, or death of the patient. Notification should be given also by physicians as heretofore. The diseases thus to be reported are diphtheria (membranous croup), scarlet fever, measles, rubella (German measles), smallpox (including varioloid), chicken-pox, whooping-cough, epidemic cerebrospinal meningitis, relapsing fever, leprosy, typhus fever, and typhoid fever. Physicians and authorities of hospitals should report cases of laryngeal and pulmonary tuberculosis. Heads of hospitals, schools, homes, and similar institutions should report the occurrence of erysipelas, puerperal sepsis, contagious diseases of the eye, and contagious diseases of the skin. Practitioners of veterinary medicine should report cases of anthrax, rabies, and tetanus. Placards should be placed on the doors of houses containing cases of smallpox, cholera, relapsing fever, typhus fever and the plague, and under suitable conditions in the case of scarlet fever and diphtheria. Isolation of patients should be enforced when necessary through the visits of inspectors or the presence of policemen. Isolation of cases of scarlet fever should be practised until desquamation has taken place and an antiseptic bath has been given; of cases of diphtheria until two negative cultures on successive days shall have been taken; in the case of smallpox until the separation of the crusts and an antiseptic bath has been given. The enforcement of compulsory vaccination and revaccination. Teachers and children in the schools who have had diphtheria should not be permitted to return until two negative cultures shall have been obtained on successive days. Carpets, rugs, hangings, and the like should be removed from the room occupied by a patient suffering from scarlet fever, diphtheria, or smallpox after removal, recovery, or death and thoroughly disinfected under the direction of the Board of Health. The room itself and, if necessary, adjacent rooms and hallways should be subjected to similar disinfections. Support was asked for any effort promising the early establishment of a pay hospital for contagious diseases.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

At a stated meeting, held January 29, Dr. Brooke M. Anspach read a paper entitled "Tuberculosis of the Breast." He pointed out the rarity of this condition in human beings and the difficulty of establishing the diagnosis in the absence of autopsy. He reported a case in which the breast was removed for what was supposed to be malignant disease, but which on histologic examination was found to be tuberculosis. No evidence of the existence of the disease in other parts of the body could be discovered. Dr. John M. Swan presented a section from a human embryonic vesicle showing early placenta-formation. The specimen illustrated the modern conception of the development of the ovum in the uterus and which was described in outline. Dr. Joseph Sailer presented a communication entitled "Some Recent Contributions to the Subject of the Pathology of the Liver." Dr. Moses Behrend presented a specimen of ruptured tubal pregnancy. The patient had had difficulty in previous pregnancies, almost all of which terminated prematurely. She was found in collapse and, the diagnosis being made, operation was undertaken, but on account of the state of the patient no anæsthetic was employed. When the abdomen was opened an enormous amount of blood escaped. The bleeding was, however, controlled and the patient reacted and entered upon a somewhat tardy convalescence. The operation was performed under most unfavorable conditions, and there was some wound-infection and subsequent pelvic inflammation, but at the time of report the patient appeared to be beyond immediate danger. Dr. Behrend also exhibited a tumor of the brain, obtained by surgical operation from a woman who presented left hemiplegia with epileptiform convulsions of Jacksonian type and headache, but without nausea, vomiting or changes in the fundus of the eye. The growth arose from the inner surface of the dura and exerted compression on the brain in the motor area. Improvement followed the operation, although the paralysis persisted. Dr. W. M. L. Coplin presented a communication entitled "Changes in the Intercostal Muscles in Pneumonia and Inflammations of the Pleura," in which he described degenerative changes in the muscular structures contiguous to the lungs and the pleura in connection with inflammation of these organs. Dr. Funk presented for Dr. S. Solis-Cohen the liver and a lung from a case that during life was believed to be one of malignant disease of the liver. The gall-bladder was found to be enormously dilated from obstruction of one of its ducts and the lung was diminutive and cirrhotic. Dr. Alfred Stengel exhibited an enlarged spleen removed from a young colored woman who had lived in malarious district. The organ was found to be the seat of numerous formations superficially of circumscribed outline and causing umbilication. Histologic sections disclosed appearances suggestive of endothelioma.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 20, 1904:

	Cases.	Deaths.
Measles	975	25
Diphtheria and croup	447	44
Scarlet fever	448	25
Smallpox	3	1
Varicella	159	...
Tuberculosis	391	192
Typhoid fever	21	5
Cerebrospinal meningitis	...	3

Are Tenotomies for Hyperphoria Necessarily More Uncertain in Their Results than Those for Esophoria and Exophoria?—Dr. Samuel Theobold states that one reason why tenotomies upon the lateral muscles are more satisfactory in their results than those upon the vertical muscles is that we can obtain greater aid from the use of glasses; another is that the lateral muscles are more fully under the control of the will; so that, if we have a moderate over-correction or under-correction, the eyes come to our assistance and help us greatly. On the other hand, in operations upon the vertical muscles the eyes afford us much less help, and about all that we can do with glasses, apart from the assistance gained from prisms, is to correct any considerable amount of anisometropia that may be present. One trouble that we meet with in tenotomies for hyperphoria is that a slight over-correction, amounting, perhaps, to less than a third of the original defect, seems at times to cause the patient more annoyance than the much greater defect for which we have operated. Another difficulty which besets us is that, when we operate upon the inferior rectus, we may secure just the balance we want for distant vision, but find things are not right in near vision. On the other hand, when we divide the superior rectus, the result may be all that could be desired in near vision; but when the eyes in distant vision come to a higher plane, there is trouble.—*Maryland Medical Journal.*

Experimental Note on the Treatment of Diabetes.—Alfred C. Croftan states that there is a means of influencing sugar destruction by human organ extracts *in vitro* by the addition to the solution of very small quantities of certain chemicals, *i.e.* drugs. The suggestion naturally offered itself to administer these remedies in glycosuria with the object of reducing sugar excretion. The simplest method, though not the most exact one (for the amount entering the circulation cannot be determined with accuracy), was to give salicylates, alkalies, or carbolic acid in definite percentages by mouth; the more complicated one was to administer these substances in normal salt solution intravenously. The former method has been used, and much empiric literature exists on the effect, notably of the salicylates and of carbolic acid (phenols), on sugar excretion. Some authors report exceedingly favorable results, and the author's personal experience has been sufficiently satisfactory to warrant the administration of carbolic acid or of salicylates in diabetes as the remedy *par excellence* for glycosuria. It is not impossible that these inorganic bodies that have hitherto been considered mere refuse (ash) play an important, a fundamental, rôle in the regulation of the life process of the cell. The ferments are fragments of protoplasm, and protoplasm has all the properties of the ferments. It is quite conceivable, therefore, that these specific salt solutions not only stimulate function in the way I have outlined in the case of sugar destruction, *i.e.* by increasing ferment action, but also by directly stimulating protoplasm when it is still alive. Should this proposition be verified, then we would have in such solutions a means to raise certain functional activities when they are depressed.—*Medicine.*

Chloroforming Plants.—A despatch to the *Sun*, January 10, states that the *Lancet* prints interesting details of the result of investigations as to the action of ether and chloroform in forcing plants to flower earlier than is natural. Dr. Johansen of Copenhagen, noticing that many plants budded after a period of repose, such as occurs in the winter months or even in an unfavorable summer, conceived the idea that by inducing such a condition by means of anæsthetics plants would be renovated, stimulated, and rendered capable of developing buds with greater vigor. Experiments with lilacs, lilies of the valley, and azaleas confirmed the theory. The French horticulturist Le Blanc, at Nancy on February 19 of last year, chloroformed some azaleas and exposed them to the action of the vapor for forty-eight hours. Then he removed them to a greenhouse which was at a temperature of 65° Fahrenheit. From March 5 the flowers began to expand, and obtained their full growth on March 8, whereas the flowers which had not been chloroformed did not expand until March 21. The economy in the matter of fuel that can be effected by this method of forcing the growth of plants, etc., it is stated, will cover the cost.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 20, 1904:

THE TREATMENT OF GUNSHOT WOUNDS BY BRITISH SURGEONS DURING THE WAR OF THE REVOLUTION, 1775–1783.*

BY STEPHEN SMITH, M.D., LL.D.,
NEW YORK.

J. St. JOHN NEALE, Esq., was surgeon of His Majesty's Fifth Regiment of Light Dragoons during the War of the Revolution. On the 19th day of February, 1804, he issued from his residence, 61 Frith Street, London, a work entitled "Chirurgical Institutes, Drawn from Practice, on the Knowledge and Treatment of Gunshot Wounds. Illustrated with Some Singular Cases and Cures of Gallant Warriors." "The Treatise," as the author calls it, is dedicated to Field Marshal, His Royal Highness Frederick Duke of York, Commander-in-chief of His Majesty's Forces, etc. In his dedication the author speaks of himself as "an individual of inconsiderable station in the dominions of our justly revered and beloved sovereign, yet a most dutiful and loyal subject," and he begs the Field Marshal "graciously to accept the following treatise on the knowledge and treatment of gunshot wounds, founded on long practice and experience during the last war in North America."

The occasion of writing this work seems to have been the threatening attitude of Napoleon, whom he characterizes as "an insidious, faithless, and audacious foe, who dares to threaten the destruction of our religion and nation." Alluding to the qualifications of the head of the "Department of Surgery," he asks to be pardoned for expressing the wish "that the royal army may never want a director at the head of the useful and important department of surgery, who has seen actual service, and maturely observed and experienced, the nature, symptoms, and treatment of gunshot wounds; as this part of surgery does not so particularly belong to the city surgeon, or even to the army surgeon, whose experience has never extended farther than the parade at home. . . . Now, as these wounds are artificial, so it is obvious that they should meet with an experienced practitioner of art to undertake them; which experience is the only sure basis on which the army surgeon can ground his practice, and from whose assistance, when so improved, there will be the greatest probability of success. It is he alone, permit me, Royal Sir, to remark, who can check groundless fear in the patient and banish real danger by his judgment; who can foretell symptoms and anticipate fatal accidents; proving a comfort to the soldier in the day of battle, as well as a friend in his more peaceful occupations.

In his preface or "advertisement," as he terms it, the author states that "The account of the accidents which form a considerable part in the very interesting subject of the following pages . . . was penned chiefly in a camp, in all the hurry and bustle of active warfare; without at the time, any thought of ever publishing them farther than among my private friends, and perhaps in conversation. But in consideration of the present awful crisis, when this great and high-spirited nation is threatened with invasion by a fierce and haughty foe, and every man's breast burns with ardor to contribute, in some manner, to repel his efforts, I have collected all my scattered notes written in the American War, and made such professional observations on them as I trust may prove beneficial." He concludes his "advertisement" with the following patriotic allusions to the medical profession: "The heart of every medical man, I am satisfied, glows with a warm desire to be qualified, and to be enabled to render every possible assistance and relief from surgery, to those brave and gallant warriors who are emulous of lavishing their lives in the glorious cause of their beloved sovereign and his dominions, and are eager to maintain the hitherto untarnished honor of England, with their wonted alacrity, and with that intrepid and well-regulated valour, which has long been the noble and distinguishing characteristic of her sons."

The "Treatise" consists of two parts, the first being devoted to a discussion of the nature of gunshot wounds and general rules of treatment, and the second to gunshot wounds in different regions of the body, illustrated with cases that came under the treatment or observation of the writer.

Following the order of subjects of the treatise, we have, first, a discussion of the nature of gunshot wounds. The author discards the theory that these wounds are poisonous, giving as his reasons that the articles composing gunpowder are medicinal, and that leaden balls often remain long in the flesh without harm. He does not mention the projectiles used except in the following statement:

"The American troops, in several engagements, adopted a method of putting two slugs in every ball cartridge, and often four. These were made by cutting a musquet ball into four equal parts, the angles of which made often a disagreeable wound, to some of our brave fellows."

He speaks of the eschar as "a portion of flesh beaten and crushed by a bullet or any extraneous body, and which lines all the inside of the wound and prevents all circulation or commerce with the circumambient or soft parts." He states that the eschar "obdurates the mouths of all the vessels in contact with it and thereby stops the circulation on the surrounding parts." He adds "the circulation becomes impeded by the stricture of the reticular substance and by the tonic convulsion of nervous parts; these causes conspire at once to produce that ecchymosis so common in gunshot wounds, and the hideous swelling which I have often observed to drown the whole member."

In regard to the shock following gunshot wounds which he calls "commotion," he says, "Health is so great a blessing that we can never be deprived of it without regret. Upon this principle, which nature has set up in all mankind, it is, that so soon

*Read before the New York County Medical Association, January 18, 1904.

as one feels himself wounded by fire arms, he is struck with a panick oppression, too violent to be smothered; at that very moment the reason of the bravest man that ever entered the field naturally feels some degree of agitation and confusion, and sometimes, on that very account, there follows a sudden depravation, or a total suppression, in many, of nature's operations. Some of the wounded feel a general numbness and weight; others are seized with frequent syncope; one falls into convulsive motions, such as hiccup, vomiting, irregular shiverings, or a tonic stiffness in the whole body; while another becomes yellow, green, or of a plumbane colour."

In his observations on the wound, he dwells especially on the tension, swelling and, sometimes, mortification and attributes them to extravasation and inability of fluids to circulate. He adds: "When the inflammation, tension, and swelling run high in these wounds that have not been properly dilated, or from want of assistance on the spot, these parts may mortify for want of circulation, even before the skin becomes discolored, and all our cataplasms, fomentations, and our Divine remedy, the bark, with every other reinforcement of our art, may prove ineffectual."

Discussing the dangers of hemorrhage from gunshot wounds, he makes the following allusion to the precautions which he took with the troops of his regiment:

"When I had the honor to attend on the 16th, or Queen's regiment of light dragoons, in North America . . . I instructed all the non-commissioned officers in the application of the tournequet, and as detachments of this gallant corps were constantly exposed on patroles and reconnoitring parties, every one carried one in his pocket, by which means several lives were saved."

Mr. Neale gives a remarkably favorable prognosis of gunshot wounds, as the results of his experience during the war. He remarks as follows: "When the habit of the patient is good, there are no wounds made on the human body that heal more kindly than those made by gunshot on fleshy or muscular parts, provided, the surgeon understands his business." It is not difficult to explain the reason of his optimistic view of these wounds when we study the conservative methods of treatment pursued.

The author states that there are four indications to be fulfilled in order to perform a cure, viz.: (1) To change the figure, and as much as possible, the nature of the wound, by proper dilatation, making sometimes a bleeding wound of that which was a contused one. (2) To remove, if possible, all extraneous bodies. (3) To stop the hemorrhage. (4) To prevent the accidents which may arise and to remedy those which already appear."

In discussing these four indications Mr. Neale lays the greatest stress on the first, or "a plentiful dilatation as soon as possible after receiving the wound." He says: "The late Mr. John Hunter, for whose memory I have the highest respect, it is well known, condemned the practice of dilating gunshot wounds, which opinion, every gentleman of the profession, who has seen active service, I am well assured, must consider as one of the most absurd ideas ever sent forth to the world, and from one of so much celebrity, it must have proved of the most dangerous tendency."

The procedure is described as follows: "The direction of the shot being found out as near as possible, the external wound must be dilated, and then a finger introduced. The finger, which, by the delicacy of its touch, is able to distinguish the crushed from the sound flesh, is the best probe we can use. It serves to conduct the bistoury, and if nothing forbids, to dilate as far as the bottom of the wound, even upon the bullet itself, which could not easily be laid hold of, because it is close set in the flesh."

In regard to the incisions to be made he says: "They must be deeper, or superficial, according to the exigence of the circumstances. We should not spare the fleshy bodies of muscles, and whenever they are covered with a common membrane, or aponuroses, as those of the leg and forearm are, we must unbridle and cut up that membrane freely, if we would prevent abscesses that must otherwise unavoidably be formed in the interstices of muscles. The fascia of the thigh must also not be spared. The same rule should be observed with regard to all aponuroses, wherever they be; but then, it must be allowed, they require great skill and circumspection to cut them up in a proper manner. If they are divided only lengthways, according to the direction of their longitudinal fibers, this incision, I have found by experience, does not unbridle them enough; they should, therefore, in particular cases, be cut in a transverse direction also, or obliquely; and sometimes even in all possible directions, like the radiated light of the sun."

He advises to spare the tendons as much as possible that the motion of the limb may be preserved, but states that there are cases in which the circumstances are such that the surgeon cannot avoid cutting them to secure that free opening of the wound necessary to its cure. He gives as an example "a wound with great havoc made among the bones of the tarsus or metatarsus; it is necessary then to make incisions on the foot," which involve tendons.

In discussing the second indication, or the removal of extraneous bodies from the wound, we learn that it was a cardinal principle not to irritate the wound more than was absolutely necessary. Mr. Neale even disapproved the use of bullet forceps unless the ball was loose and readily seized. In this he states that he differs from Pare, Wiseman, and Brown, "gentlemen of distinguished abilities." "If the extraneous body," he says, "cannot easily be discovered, it is much better to leave it, than to harass the parts by searching too curiously with clumsy and rough instruments, as long probes, forceps, and the terribellum or screw, by which means there must have been terrible havock committed on wounds, not unfrequently ending in destruction." He adds: "It seems to have been considered by them as the greatest object to get out the ball, when in fact it is no object at all when lodged in fleshy parts, unless it causes much disturbance of the wound." If rags are carried into wounds and the finger cannot discover them after proper incisions, he advises not to distress the parts by too much searching, as they will escape afterward with the suppuration. He urges surgeons not to change dressings too often, lest the wound be unduly disturbed, and gives as a rule to dress only when pus appears through the dressings. Our author lays down the following general principle: "As the cure of wounds, as well as other diseases, is in reality the work of nature, assisted by art, it becomes the business of the practitioner to study her indications, watch her motions when she calls for aid, keeping always in mind never to do too much."

The control of hemorrhage should always be by ligature when possible. In many cases when the wound is deep the surgeon is advised to put the finger on the bleeding point, and then pass a needle carrying a ligature through the tissues under the finger and tie a knot. If the wound has been incised sufficiently, as recommended, it will be so open that the ligature can generally be used: i

however, the artery cannot be found and the end of the finger cannot be placed on the bleeding point, then recourse may be had to a styptic, which must be applied directly at the point of hemorrhage. If the wound is very deep and the bleeding cannot be controlled by ligature or styptics, it must be filled with very soft lint, which should not be *pressed* into the wound.

The fourth indication, or the prevention of "the accidents which may arise and to remedy those which already appear," involves a discussion of the general and local remedies to be employed. In both of these respects the most conservative methods were pursued.

The general treatment was directed to allaying pain by opium, which he calls a Divine remedy; to relieving congestion by incisions of the wound; to nutrition by increasing the digestive functions, and, finally, to allaying fever and high grades of inflammation by timely venesections. The latter of these remedies is to be used with the most careful attention to the condition of the wound and the constitution of the patient.

The local treatment or the direct treatment of the wound was of the same judicious and conservative character. After a "plentiful dilatation of the wound" by incisions at as early a period as possible and an arrest of hemorrhage, the first effort of the surgeon was to hasten the removal of the eschar by "animated digestives," which have a power of correcting the juices and defending the sides of the wound against the corruption which might otherwise prevail."

We are not informed what were the ingredients of these digestives, for he remarks "every surgeon must know them; and almost every author is full of them." He says, however, "Among these warm and animated digestives, I reckon a little of the spirits of turpentine, mixed with them, as one of its most excellent ingredients, as a topical application, in all cases where tendons, membranes, aponeuroses are concerned." He advises against the use of greasy and putrescent applications, as they melt down or attenuate the suppuration.

The eschar having been removed, the author advises to dress the wound with great tenderness, using mild, balsamic applications, bearing always in mind that it is not the medicines which we put to the wound that will cure it, but "nature alone must form the fleshy granulations that fill up the wound." We must remember, he adds, that everything we apply *there* is an extraneous body, whether it be lint or medicine."

Finally, great stress is laid upon that Divine remedy, "the Peruvian bark," which was given to the full extent the patient could take it when suppuration commenced.

In the second part of his work the author treats of wounds of different parts of the body commencing with the head. Contusion of the skull is first considered, and the rule of treatment is given as follows: "Every contusion of the skull requires the trepan, because it must be attended, sooner or later, with a disorder of the dura mater." He adds: "I have, in a great many instances, observed this membrane suppurate after a blow which was no more than bruising, where I had found the pericranium separated, and the bone sensibly discolored. I have seen the same happen after a blow from a sword, which had only scooped out a small piece of the diploe, the inner table of the skull remaining entire without any fracture. In this doctrine I perfectly agree with all the great practitioners, viz., the late Professor Cleghorn of the University of Dublin, Professor Monroe of Edinburgh, Mons. Petit, etc., and affirm, that when a bullet grazes upon the head, so as to lay the skull bare, there ought to be no hesitation in applying the trepan; because after such strokes, we have almost always seen the dura mater suppurate at the injured part."

The author illustrates his views by the following cases: "During the campaign of 1777, a small detachment of the 16th regiment of light dragoons, reconnoitring about eight miles from Philadelphia, in America, fell in with a company of the enemy's rifle-men, whom they immediately charged with their usual gallantry; several of these were wounded, and the rest made prisoners by our troops. It happened at this time to be my turn of duty, and Mr. Welford's, an ingenious surgeon in our service, to attend the prisoners of war. Among the wounded brought to the hospital, six were cut in the head, three of whom were fractured, as was visible on the parietal bones.

"They were all plentifully bled and next day their bowels emptied. On the third day we applied the trepan. In two of them the fracture ran so long, with a considerable depression, that it was found absolutely necessary to apply the trepan three times to enable us to raise the depressed and broken pieces of the bone, its whole length having suffered from the blow. . . . The other three prisoners had the scalp cut about three inches, two of them on the left parietal bone, and the other on the right. But as Mr. Welford and myself could not perceive either fracture or contusion of the bone, we resolved to content ourselves for the present with using the cooling regimen, and treating them as simple wounds. However, on the ninth day, in the morning, their wounds put on an unfavorable aspect, they had a restless night, were feverish, with other concomitant symptoms, which usually attend on injuries of the dura mater. Mr. Welford being of my opinion, to proceed immediately to examine the bone, we began with the patient whose symptoms were most severe.

"The bone was no sooner laid bare, when we discovered the pericranium a little loose, and under it the bone felt as if it had been rasped with a file, and appeared a little discolored, but we could not perceive the least depression or fracture. The trepan was instantly applied, and the dura mater found perfectly detached, with slight suppuration. The trepan was soon after applied to the other two, and appearances found nearly similar. They were all robust healthy young men, and their cures completed in a much shorter space of time than is usual from such accidents. The cure of the three last was accomplished a long time before the former."

The author states that the battle of Germantown, fought on the 3d of October, 1777, "afforded another remarkable instance of the effect of bullets grazing on the skull." This was the famous attack of the Americans upon a stone building in which the British took shelter and fired upon the attacking party from the windows. Among the Americans taken prisoners Mr. Neale states that ten men of the Fifth Virginia Regiment were wounded in the head, the balls grazing the skull. The wounds were all in the area of the parietal bones. Five of the number were trepaned on the fifth day before any bad symptoms appeared, and five were trepaned when bad symptoms indicated suppuration. In no case was there either fracture or depression. In the first five cases slight suppuration was found, but in the other five suppuration was abundant. They all recovered and did well. From his experience the author concludes that in similar cases the trepan should be applied about the fifth day.

Mr. Neale combats the statement of some au-

thors that a large fracture of the skull is less dangerous than a slight one with very pertinent examples. "In every fracture of the skull," the author directs that "the dura mater should be sufficiently disclosed by the trepan or by raising up one or more of the fractured pieces," for the reason that in these cases suppuration is very likely to occur and prove fatal, owing to the inability of the pus to escape.

The author states that if the ball is sunk and lost within the skull the wound is always mortal, because of the inability of extracting it. Hence he lays much stress upon the symptoms of penetration of the brain which are loss of the intellectual faculty, inabilty to stand erect and convulsions. "For the honor of the profession therefore," he says, "let no surgeon ever suppose that a ball can be lodged behind the inner table of any part of the skull, when the patient, after receiving the wound, can stand erect, and continues the enjoyment of his intellectual powers." He relates the mistake of Mr. Rush in the treatment of John Mellish, Esq., who was shot in the forehead by a footpad on the Colnbrook road. The ball did not penetrate but rebounded, yet the surgeon treated it as a penetrating wound and it proved fatal, probably from failure to trephine and thus relieve a subdural abscess.

In wounds of the neck the writer advises the utmost caution in the use of the probe and remarks, "All that art can do, after the external incisions are made, is to assist nature with emollient poultices, often renewed, and the application of such medicines as will bring on a speedy separation of the eschar, without raising a plentiful suppuration, for that might occasion such a fusion of the matter as would lay the larnyx, blood-vessels, and muscles all bare." He reports the case of Captain Hawkshaw of the Fifth Regiment of Infantry, who was wounded in the neck by a musket ball, which entered the Coraco hyoideus muscle, on the right side, passing through and through behind the gullet, which it grazed. Blood gushed out in torrents from his mouth and nostrils as well as from the wound. The hemorrhage was checked, as no large vessel was involved, the wound was enlarged as much as the parts would admit, a soft dressing applied and the neck covered with an emollient poultice. Although he had lost a large quantity of blood, he was bled copiously, and laudanum administered. Fearing a secondary hemorrhage, a surgeon watched him constantly. On the following day he could swallow only with great difficulty and nourishment had to be given by a tube. The dressings were removed on the third day, and suppuration having begun, warm balsamic digestives were applied. For thirty days he was fed on cow's milk, panada with an occasional spoonful of wine. The Peruvian bark was now administered copiously, and in three weeks he was able to swallow solid food. In another fortnight his wound was perfectly healed, and in every respect he was restored, as the author states, "to his pristine health."

Wounds of the clavicle are dangerous only when the ball penetrates the chest. If the bone is fractured simple care must be taken to keep the shoulders back with a bandage lest the arm sink in toward the breast. He relates the case of a soldier whose collar bone was shattered by a glancing ball at the battle of Germantown, and says he could mention many more.

Wounds of the scapula are illustrated by a grapeshot fired from a cannon at the reduction of Fort Washington, New York, November 20, 1776. The writer saw the patient in consultation on the following day, and found the body and spine of the scapula shattered. He advised larger incisions to dilate the wound, and the free use of opium and Peruvian bark later when gangrene threatened. Splinters of bone were discharged from time to time, but in fourteen weeks he was restored to health, and during that time he took upward of four pounds of Peruvian bark.

If the wound penetrates the cavity of the chest, three points are to be considered: (1) fracture of the rib; (2) the injury inflicted on the internal parts; (3) the effusion of blood. The first indication requires incisions of proper length to dilate the wound so that the splinters of the fractured rib may be removed, and if the wound is sufficiently low "it may facilitate the discharge of whatever may be effused on the diaphragm." He states that "The surgeons of the allied army in America, made use of a narrow linen rag in dressing these wounds, somewhat like a seton, one end of which they introduced by the wound into the breast. But I did not see that any advantage was reaped by this practice; but rather the contrary, for we not only run a risk in introducing it, of separating the pleura from the inside of the ribs, or at least of disturbing that membrane, but farther, that seton in the breast is, truly, an extraneous body."

Instead of the tent he recommends nothing but a stoppel of lint, wrapped up in a piece of fine soft linen, and kept firm by an adhesive plaster. He was also opposed to throwing injections into the breast as recommended by some authors, believing that the compression of the lung thereby is very harmful. He adds: "In the cure of all wounds inflicted on the breast, whether they penetrate or not, whether the lungs are wounded or not, whether there is or is not a hemorrhage, we should, by means of a pretty tight bandage, in some measure check respiration."

The author speaks very favorably of wounds of the lung when the ball has passed through it and out again, and says he has seen many cases of recovery. He remarks: "At the battle of Brandywine, fought on the 11th of September, 1777, in which the Americans suffered considerably. . . . The first battalion of British grenadiers, in storming the enemy's works, had seven brave fellows shot through the lungs. The balls passed through and through. Five were shot through the right lobe and two in the left. The five former recovered but the two latter died."

It is nature alone that must cure the wound here he says, as well as those of the other viscera, the duty of the surgeon being to allay the inflammation.

If the ball has penetrated a considerable way in the lungs and rests there, the prognosis is unfavorable, because we can have no hope of extracting. There is only one case, in his opinion, in which we should even attempt extraction, viz., when the lung adhere to the pleura at the wounded part, and when at the same time, the ball can be felt by the rough smooth end of a large sound. He states that among the wounded of the Americans left in the field after action after the battle of Brandywine, three were suffering from balls lodged in the lungs, two were in the right and one in the left lung. He succeeded in extracting the balls from the right lungs, and both patients recovered, but he failed to extract the ball from the left lung and the patient died.

With regard to the dressings of penetrating wounds of the chest, he says we should not introduce such topical medicines as will promote the suppuration, as in wounds of the external parts, lest they be effused upon the diaphragm and excite a dangerous cough. We must be satisfied with pouring in a

drops of some suitable balsam. If, however, the lung is adherent to the pleura and the eschar still subsists proper injections may be made.

The author illustrates the treatment of these wounds by giving the case of a soldier, shot through the right lung during an attack upon the American general, Anthony Wayne. The ball entered between the fourth and fifth ribs, and at the point of exit fractured the edge of a rib. This patient was transported thirty miles, but in ten weeks he had entirely recovered and returned to duty. In an attack upon a stone house where the Americans were quartered, a soldier received a ball from the third story, which struck him between the seventh and eighth ribs on his right side, where it entered and lodged in his body. He passed large quantities of bloody urine for several days. Several surgeons saw him and regarded the wound as fatal. He was treated by copious venesections, losing 40 ounces of blood; opium at night and, after the seventh day, Peruvian bark in warm cow's milk which the author says, "served both as nutriment, and contained also the virtues of this admirable remedy, which agreed with him remarkably well." In ten weeks his recovery was complete.

Mr. Neale saw many cases of wounds of the upper and lower jaws and of the tongue. He says, "In some of these wounds I have seen the inflammation of the temporal muscle and of its tendon bring on convulsions; which, whenever they do happen, we must endeavor to prevent or appease by general remedies, and by emollient and discutient poultices." In wounds of the upper jaw his effort was to prevent fistulas. In fracture of the lower jaw approximation was maintained by strings around the teeth of the fragments and support of the jaw by apparatus. In wounds of the tongue scarifications were freely made to prevent gangrene and to reduce the swelling. He advises the surgeon to take great care to find out any extraneous bodies, such as the ball or pieces of bone or a tooth.

As to the dressings he says, "It is nature alone that dresses these wounds with her saliva; and the detersive injections which the surgeon applies serve only to keep the wound and mouth clean."

Wounds of the mediastinum our author regards as extremely dangerous, because this part is a membranous texture and very much subject to inflammation. Should an abscess be formed in the duplicature of this membrane, it may sometimes be evacuated by trephining the sternum, but more often they open into the chest, and cause an empyema, and notwithstanding all our art will destroy our patient. Gunshot wounds of the heart are always fatal and are more sudden than those inflicted by a sword "on account of the shock and perturbation, which always attend such a wound. Wounds of the tendinous portion of the diaphragm are always fatal, but those in the fleshy parts may recover. As to treatment, "Nothing but nature herself, assisted with general remedies, is able to cure wounds of this nature."

Wounds of the sternum require much the same treatment as wounds of the skull, but "The incisions that have been hitherto recommended, may be more requisite here than elsewhere, with a view to discharge the soft parts of their load of fluids and to prevent spreading suppurations among the investing fat and membranes of this part." All fragments must be removed, and if an abscess forms behind the bone as a consequence of the contusion its evacuation must be by trephining.

"A gunshot wound inflicted on the body of the spine, or back-bone," says our author, "in whatever part it may be, betwixt the first vertebræ of the neck and the os sacrum, are all mortal, if at the same time the spinal marrow has been lacerated." Paralysis may occur from simple bruising, or on the fracture of the processes, or even when the vertebral artery is divided. He merely advises that in the treatment the incisions must be free, not sparing the tendons so numerous here.

Mr. Neale regards as mortal, wounds of the stomach, intestines, pancreas, and liver, when the latter is wounded on its concave side, though he admits there have been a few instances of cure. Wounds of the large vessels of the abdomen are always fatal in his experience.

He thinks it vain to search for the ball, but advises to enlarge the wound except the peritoneum, unless the wound be upon the convex part of the liver not in contact with the diaphragm, in which case the wound of the peritoneum may also be enlarged. Wounds that penetrate the kidney require a special method of dressing to protect them from the irritation of the urine; for this he recommends besmearing the surfaces with greasy medicines after the wound has been well incised.

Wounds penetrating the pelvis are likely to be complicated with perforation of the bladder, and the author has seen many recover by enlarging the wounds so as to make a free exit and the use of the cathether to prevent distension of the bladder. Wounds of the rectum higher than the surgeon's finger can reach, are to be treated in the same way as wounds of the bladder, but when the wound is near the anus, incisions should be made not unlike those required in fistula. In the latter case "There are two very essential points to be observed in the course of dressings; the first is to preserve the diameter of the anus as much as possible by introducing a suppository perforated in the form of a cannula or pipe, as soon as the orifice seems threatened with constriction. The second is to prevent a looseness, that might disturb the condition of the wound."

Wounds of the extremities were treated on the general principles laid down in the early chapters of the work. Large incisions were made at once to give free access to the bottom of the wound; all accessible foreign substances were removed; simple warm digestive dressings were applied until the eschar separated; then balsamic dressings were used with the free administration of Peruvian bark. When the arm bone was broken he inclosed the part with two flexible splints, sometimes using paste-board, and sometimes the bark of trees retained by tapes. He gives as an example a captain, who was wounded by a grapeshot at the storming of Redbank Fort, on the north side of the Delaware, near Philadelphia. The ball entered the biceps muscle about five inches above the elbow, and running obliquely upward, made its exit out at the triceps muscle, causing a comminuted fracture. He recovered in thirteen weeks, though there were large exfoliations of bone. The treatment was full dilatation of both orifices of the wound, copious venesections and an incredible amount of Peruvian bark, viz., four pounds and a half.

Gunshot wounds of the forearm are regarded as more susceptible of bad symptoms than those of the arm, as the muscles of the forearm are conjointly wrapped up in a tendinous membrane—that is, an aponeurosis or expansion, detached from all the flexor and extensor muscles." The danger lies, the writer believes, in an inflammation of this membrane, and the accumulation of pus under it, causing the forearm to "swell up in a greater or less degree, and sometimes becomes so hard that a gangrene must speedily succeed if not prevented." Hence the

importance in the treatment of these wounds of pursuing the treatment so much insisted upon, viz., early dilatation. He says, "the incisions that are made should penetrate to the bottom, and unbridle all the parts, but chiefly the common tendinous membrane in every direction, especially when the radius or ulna is fractured." He relates the case of a cavalry officer who was on patrol at Brunswick in the Jersies, when a number of American militia attempted to take him prisoner. He escaped, but as he fled on horseback, a volley was fired at him and he received three wounds, one of which was in the fore-arm near the wrist. In spite of free incisions, venesections, and emollient cataplasms, the whole fore-arm became involved in the suppuration, and on the forty-third day after the accident he amputated the arm, and in eighteen days the wounds were completely healed.

Wounds of the wrist, metacarpus, and fingers are to be treated with free incisions, and every effort must be made to save the fingers, or even parts of them.

Gunshot wounds of the thigh were treated on the same general principles as those of the arm, but still greater stress is laid on the necessity of large dilatation. Owing to the large muscles, much fat and extensive aponeuroses of the thigh, the author says: "We must inflict more liberal incisions here than in another place, especially if the bone is broken or laid bare. I know that large wounds are followed by large suppurations, and that large suppurations exhaust the patients; but I know also, by experience, that when ample incisions are made, the parts will be much less disturbed in extracting the extraneous bodies, which will spare a great deal of pain and hasten the cure. . . . By these incisions we prevent congestions and suppurations that would in the end oblige us to make incisions of a much greater extent. . . . Supposing the femur is broke in pieces, and there is reason to hope the thigh may be preserved, we must, after all the intentions of art are fulfilled, manage the affair in such manner that the other remaining pieces of bone be kept fixed in their natural place."

The author's illustrative case is related as follows: "At the battle of Prince Town, in the Jersies, North America, on the 3d of January, 1777, memorable for the distinguished valour displayed by the 17th regiment of infantry, and two hundred of the 16th regiment of light dragoons, under the command of Colonel Mahood, who, on their march to join Lord Cornwallis at Brunswick, about fourteen miles distant, were unexpectedly attacked by the whole army of General Washington, and notwithstanding the superior numbers of the Americans, amounting by report to upward of ten thousand men, this gallant detachment cut their way through them and made good their retreat to Brunswick. This was reckoned one of the most gallant exploits of the whole war.

"In this action Serjeant John Miller . . . . was wounded in his right thigh, by a grapeshot fired from a cannon. The ball entered the vastus internus muscle a little above the center of the limb, and running obliquely upward, made its exit through the externus muscle of that name on the opposite side. The bullet pierced very deep and fractured the bone, and unfortunately for him, it shattered a penknife that was in his pocket, some of the splinters of which were carried into the wound, and dispersed among the interstices of the muscles. There was a prodigious laceration made in the thigh by this blow, and the muscles, both where the bullet entered and passed out were jagged and torn to a much greater degree than any other wound that occurred during the war from a similar shot.

"As soon as possible, I made a very large dilatation of both the orifices, and for the present applied a soft dressing, and secured the broken bone, as well as the great emergency of the time would admit, till we arrived at headquarters, when he was bled largely. . . . In the morning his fever ran high, and the inflammation and swelling of the limb I perceived to increase with great rapidity. I bled him again copiously, after which, a few grains of nitre, with testaceous powder, was taken every two hours.

"In the morning . . . a considerable discharge of thin bloody ichor came away, and with it a piece of his leather breeches, . . . the wound was now dressed with warm balsamic digestives, and over all an emollient poultice. On the fifth day a suppuration took place, and he began to take the bark which was increased by degrees to as much as his stomach would bear. This method was continued for fourteen days . . . when an abscess began to form on the thigh, about five inches below, but before it could be opened it began to discharge itself by a sinus into the internal orifice of the wound. The sinus was laid open its whole length, and in two days after, a piece of the handle of his penknife . . . came away with the dressings . . . and three more portions of the same extraneous body in the space of a few days afterward was extracted, a considerable distance from where the ball entered. . . . A large exfoliation of the bone followed this wound, which soon healed over, and his cure was perfectly completed, during which the took four pounds and ten ounces of the bark."

Wounds of the leg, like those of the fore-arm, require ample incisions on account of the extensive aponeuroses which envelop the muscles. Wounds of the tarsus are much more serious than of the carpus, and generally demand immediate amputation, but as some cases have been saved, the surgeon should be governed by the conditions of each case. Wounds of the metatarsus and toes are to be treated like those of the metacarpus and fingers.

The subject of amputations is alluded to only incidentally. In a note the author remarks: "There are no stumps which heal more kindly than those in consequence of an operation from gunshot, when performed early. In the mild season of America, they seldom exceeded a fortnight before the stump was completely healed."

The author closes his treatise with a chapter entitled, "An enquiry into the nature and causes of suppuration in gunshot wounds." At the close he thus gives his conclusion: "The efficient cause, therefore, of a suppuration, is the oscillatory motion of the sound vessels, especially of the sanguiferous kind, which, being more distended and beating more frequently than usual, when they dilate themselves, strongly compress and agitate the ruptured vessels which are full of stagnant fluid; so that it is easy to conceive that in a suppurating part there must be an inflammation, or, at least an intense heat."

From this review we conclude that the treatment of gunshot wounds during the War of the Revolution, 1775-1783, by British surgeons, was very conservative, and in accordance with the views of pathology then prevalent. It was believed that gunshot wounds caused a great perturbation of the fluids and solids of the part and commotion of the whole system, especially of the nerves. The first principle of correct treatment, therefore, was rest both to the body and to the wound. Transportation of the wounded was avoided, as far as possible, and, when imperative, was made as free from physical discomfort as circumstances would permit. Officers were carried by hand on feather beds in some instances. Opium for the relief of pain and to secure

sleep was called a "divine remedy." The perturbation caused by inflammation was relieved by copious venesections. To the practitioner of to-day the enormous loss of blood which these patients sustained at the hands of surgeons, would seem to be more fatal than the wounds. During the suppurative period Peruvian bark was a sovereign remedy, and the limit of its use was the capacity of the patient to take it. The greatest possible reliance was placed upon it, and more largely to that than to any single remedy does our author attribute his success. It is interesting to notice in this connection that alcoholic stimulants are not mentioned in this treatise.

The local treatment of the wound was also conservative in the highest degree, the great object of the surgeon being to avoid disturbing the injured parts. For this purpose the wound was at once freely opened so as to remove extraneous substances, the ligature of arteries, and to enable all the subsequent discharges free escape. The wound was never to be crowded with lint or other substance, lest the granulations should be injured; the utmost care must be taken in withdrawing matters from the wound to avoid opening closed vessels; dressings were to be changed only when the discharges appeared outside of the bandage. Though no disinfectants were used as such, yet balsamic preparations were employed in large quantities for their supposed powers of sweetening the wound and its discharges, and their detergent effects.

A scientific estimate of the comparative value of different methods of treatment requires a similarity of condition which we cannot obtain. But from this review it is apparent that the surgeons of the War of the Revolution had a remarkable success in the treatment of gunshot wounds, and it is doubtful if the wars of the last century would show better results, wound for wound, even if we could make the most accurate comparison.

640 Madison Avenue.

THE RATIONALE OF THE NATURAL ARREST OF CONSUMPTION; A STUDY EXPLAINING THE EFFECT OF SEA VOYAGES, OUT-DOOR LIFE, ETC., ON THE DISEASE, WITH SUGGESTIONS AS TO IDEAL TREATMENT.*

By W. B. McLAUGHLIN, M.D.,
Austin, Tex.

There is probably no field in medicine that has been so thoroughly covered by experimental work as has been tuberculosis. The literature and experimentation on this subject is immense, but it seems to me that everyone has worked more to discover some new fact than to utilize the facts discovered by his predecessors in the field; or if not that, he has worked to prove some favorite theory; for example, numerous investigators have devoted much time to the perfection of an antituberculosis serum; yet so far as I know not one has brought forward any evidence to show that such a serum plays any part in the natural arrest of a tuberculosis; on the contrary, the evidence shows that this arrest, when accomplished, is done by a walling off and actual starvation of the invading bacteria.

From another point of view we know that an antitoxin checks the progress of a disease by inhibiting the growth of the microorganisms causing it, but we also know that in a caseated tubercle of an arrested tuberculosis the bacilli exist long after the possibility of an antitoxin circulating in the blood reaching them has ceased to exist.

*Read at a meeting of the New York Academy of Medicine, February 18, 1904.

If we assume that the bacilli are finally destroyed by the formation of an antitoxin within the tubercle, we also assume the impossibility of reaching them by the injection of an antitoxin into the circulation. I believe it safe to assert that, when Nature does not use an antitoxin in the cure of a given disease, that man will never be able to do so. The only specific action which can, so far as I can see, be attributed to the bacillus tuberculosis, is a local one affecting the tissues in its neighborhood, causing the so-called caseous degeneration; the rest of the phenomena observed can be accounted for by the inflammatory reaction resulting from the presence of a mildly irritating foreign body.

The study of the forces employed by Nature in dealing with this tubercle is the object of this paper. This study naturally resolves itself into the study of the pure tuberculosis infection and the study of complicating infections. In reviewing the literature of tuberculosis one is immediately struck by the different degrees of susceptibility exhibited by different species of animal to tuberculous infection; also a well-marked difference between animals of the same species.

The guinea-pig when subjected to an inoculation with the bacilli at almost any site, soon develops a general tuberculosis; the rabbit seems to be able to deal with the infection when it enters by the lymphatics, but succumbs when it is introduced into the general circulation; the goat seems immune to its action under almost all conditions.

The difference in susceptibility between civilized and uncivilized man is clearly shown by statistics. We also observe that the same animal under different conditions shows different degrees of susceptibility to the infection.

These phenomena for want of a more accurate definition, we call the resistance of the organisms to the infection: it probably comes about in obedience to the laws causing the organism to adapt itself to its environment. We know that the Laplander is less susceptible to the effects of cold than the African, and are content to say that it is a question of environment. We know that the Englishman is less susceptible to tuberculosis than the African, and we feel it necessary to assume all kinds of queer conditions in the tissues of the Englishman.

Whatever may be the cause, this resistance plays a most important part in determining the effect of a tuberculosis inoculation upon any given animal. In the guinea-pig it means death; in the goat, life; between these two extremes comes man. It seems to me that his resistance is comparable to that of the rabbit, *i.e.* able to deal with the tuberculosis if introduced by way of the lymphatics, but overwhelmed by it when introduced into the general circulation.

Let us imagine that a man has been infected by a tubercle bacillus in some part of his body, and watch what occurs. It would be picked up and carried to the nearest lymphatic gland, this gland would become the seat of a typical tuberculous process, becoming in time caseated or breaking down and discharging the so-called tuberculous pus; if no other infection has occurred, an examination of this pus will reveal the fact that it contains no tubercle bacilli but is sterile. The infection may or may not have been extended to other glands, but at this point the tuberculous process has been controlled, and under the proper condition the wound heals. If, as frequently occurs, the pus is not sterile, but contains tubercle bacilli mixed with pus cocci, the wound still heals if placed under the proper conditions, which are rest, drainage, and the prevention of infection from the outside.

If, on the other hand, the proper conditions for

healing do not obtain, the wound goes on indefinitely discharging pus containing pus cocci and tubercle bacilli.

Now, if in place of a gland, we imagine that the infection be located in some other tissue of the body, and remember that caseous degeneration is caused by the bacillus, and that the tendency of Nature is to wall off the infected area by the formation of new fibrous tissues, it follows that the rapidity with which the invading germ is walled off is directly proportionate to the vascularity of the tissue involved; we are thus in a position to foresee the slow progress of a tuberculosis in bone, or the rapid encapsulation and healing up of a tuberculosis process in the lung.

At first glance it would seem that a tuberculous process in the lung was rather a chronic one and, for many months this apparent difference between what I thought ought to be and what I knew was, puzzled me greatly. I had already reached the conclusion that the pus cocci were responsible for the duration of the disease, when I first saw an account of Prudden's admirably conducted experiments, by which he demonstrated that when the lung of a rabbit was infected with a pure culture of tubercle bacilli, that tubercles formed were walled off and remained as such; but, when the culture was mixed with pus organisms that the tubercle broke down and a cavity was formed.

This is in accordance with what we would expect in a tissue of such a high degree of vascularity as the lung. When once a tubercle located in the lung has been infected with pus cocci, we are then dealing with a disease known clinically as chronic ulcerated phthisis. The tubercle soon breaks down, leaving a cavity filled with pus, which finds an outlet through one of the bronchi. We now have a septic cavity which is subjected to constant inflation and deflation with air.

Under existing conditions in large centers of population, it is more than probable that this air will drag in some particle of dust loaded with pus cocci; keeping up and giving new life to the existing infection. To go back to our suppurating tubercle gland, which we will assume opened and discharged its contents, and that you have irrigated and dressed; now, suppose that once a day some malicious person would slip in, remove the dressings and carefully deposit a few pus cocci in the cavity, don't you think that the case would be an extremely chronic one? So it is in chronic ulcerative phthisis.

Nature has, in a more or less perfect manner, provided for the rest and drainage: First, by the formation of pleuritic adhesions; second, by the cough; but she has utterly failed to provide against infection of the tubercle with pus organisms, or its constant reinfection after once being infected; and to this failure is due the chronicity of the trouble.

Under these conditions one would expect that the success attending the treatment of a tuberculosis infection of the lung would depend on the degree of completeness with which we supply that essential for healing in which Nature has failed, viz., the prevention of reinfection.

Upon an examination of the literature on the subject, we find that this is actually the law by which we can judge the value of climate and mode of life to a tuberculous patient. Whether we put him on the coast where the prevailing winds are from the ocean, or send him to sit on the snow-covered verandas at the Loomis Sanatorium; or, in other cases, to the dry trans-pecos region, depends not on the tuberculosis process itself, but upon other conditions which affect each individual patient.

The one thing demanded by the tuberculous infection is that the danger of reinfection be minimized, and this is the one element which is common to all climates and modes of life which have been found to be of value in the treatment of chronic ulcerative phthisis. Conversely we find conditions favoring the presence of large amounts of infected dust in all places where phthisis does badly.

At this stage in our investigation it becomes proper to inquire, First, if we succeeded in preventing reinfection in the septic cavity in the lung, would that cavity heal? Second, To what extent and how, can this reinfection be prevented?

To the first, histology gives us no reason to believe that the lung is a tissue of less resistance and recuperative power than other tissues.

On the contrary, on account of its extreme vascularity, we expect it to have more. Therefore, under the former conditions, we should expect it to do at least as well as lymphatic glands do. In this connection I would quote at length from an article written by Dr. Alex. G. R. Fullerton of the Middlesex Hospital Medical School and published in the *Philadelphia Medical Journal* of November 2, 1901

"By keeping a patient who has a cavity infected by pyogenic cocci in an atmosphere of practically germ-free air, such as may be found at moderate altitudes, and by enforcing the nearest approach to physical rest possible, one cannot merely protect him against the risk of reinfection by pus organisms, but one also places him under conditions in which the work which has to be done by a damaged lung is reduced to a minimum. With the patient thus protected as far as possible against any reinfection of the cavity, one may confidently hope that the intensity of the present pyogenic infection will be reduced.

"It is a matter of common experience that when pyogenic bacteria are confined to a limited space and are kept from reinfection from the outside that their virulence becomes attenuated, and that after a time they tend to die out. Thus the streptococcus from an old empyema, old pyosalpinx, or chronic abscess of any sort, will often be found to have lost much or all of the virulence which it must have originally possessed. Charrin and Guillemomet have recently shown that the same attenuation of virulence in intestinal bacteria takes place when an animal without any special preparation is kept in sterile air and fed on sterilized food.

"In the absence of reinforcement from without the number of intestinal bacteria is markedly diminished, and the vitality of those that survive is distinctly lowered. If, therefore, a patient is kept under the conditions which I have spoken of, one may expect that improvement, so far as the pyogenic infection of the cavities is concerned, will follow. And it is probable that this is what happens in most of the cases in which apparent arrest of phthisis follows treatment in well-ventilated hospitals and sanatoria. Every one knows, however, the common after-history of such cases. . . . What has probably really happened is that with the disappearance of the secondary infecting bacteria the pulmonary phthisis has reverted to the former condition of uncomplicated pulmonary tuberculosis."

I have quoted Dr. Fullerton's article at length in order to show the trend of opinion in regard to the way an infected cavity would behave if reinfection were prevented. I do not agree with his deduction for the following reasons: (1) In the examples cited, viz., the empyema and pyosalpinx, etc., the condition of non-reinfection is absolute. In the experiments on the guinea-pig the same condition prevails.

The assumption that this condition prevails in well-ventilated sanatoria at moderate elevations is unwarranted by the facts. I cannot believe that Dr

Fullerton thinks that the pig would have manifested the phenomena observed if he had been merely removed to one of these sanatoria.

Dr. Fullerton further states that what probably happens is that the mixed infection is converted into a pure tuberculous infection. While this is undoubtedly true in some cases, I contend that those are the cases that get well and stay well. In this I am borne out by the analogy in the behavior to tuberculosis in other tissues.

We know that more people have tuberculous nodules in their lungs, no symptoms of which are manifest during their lives, then die of phthisis. It, therefore, seems to me unwarranted to say that the mere existence of this mass of tuberculous tissue in a man's lung would surely condemn him to a relapse upon his removal to a low altitude.

Could we not say that what probably takes place in these sanatoria is one of three things: (1) The conversion of the mixed infection into a pure tuberculosis; (2) the conversion of the mixed infection into a mixed infection of less virulence, consequent on less frequent reinfection; (3) the conversion of the mixed infection into a mixed infection of less virulence consequent to being reinfected with attenuated pus organisms.

It is a well-known fact that bacteria grown in unfavorable surroundings tend to become attenuated. Cold, dryness, and altitude are unfavorable conditions for the growth of bacteria, and most sanatoria possess one of these conditions.

What I believe really happens in these cases which relapse on return home, is as follows: The patient, more or less immunized to the action of streptococci, by the long duration of a suppurating cavity in his lung, goes to a sanatorium. There, as a result of less frequent reinfection or his being reinfected by less virulent bacteria, his condition improves. In these patients, even when pronounced cured, one can by careful auscultation over the site of the tuberculosis lesion, generally find pathological râles.

If one could open the lung at this stage he would still find a mixed infection, but of a low degree of virulence, and not of sufficient violence to produce sputum.

To recapitulate: We know that, in pure tuberculosis infections of the human body, Nature controls them by walling them off with new-formed connective tissue, and that the rapidity of the process is in proportion to the vascularity of the part affected.

We know that in chronic ulcerative phthisis the mischief and ultimate death of the patient is largely caused by the complicating infections. We further know that these bacteria if left to themselves and not reinforced by new infections, will become attenuated and finally die out. We know that dogs have been kept under conditions when infection by outside organisms did not occur. This is shown by the experiments quoted above; also by experiments of Wythall and Thierfelder.

Now, it seems to me that the deduction is inevitable, that if a patient suffering from chronic ulcerative phthisis be kept in sterile air and his person kept as near aseptic as possible for a sufficient length of time, he must, in obedience to the laws of healing, recovering from his lesion, so far as his ulcerative phthisis is concerned; *i.e.* his ulcerative phthisis will be converted into a pure tuberculosis, or what is known as latent tuberculosis.

Autopsies teach us that only about 40 per cent. of these cases of latent tuberculosis become active. Thus we could logically expect that out of every ten patients treated six would remain well, and four become reinfected, and be compelled to return for another period of treatment.

Many cases of ulcerative phthisis are converted into cases of pure tuberculosis by our modern methods of treatment, the results cannot be obtained with mathematical accuracy until we place our patient where reinfection is a practical impossibility.

RUNNING EAR.

By A. C. BARDES, M.D.,
NEW YORK.

ASSISTANT SURGEON, NEW AMSTERDAM EYE AND EAR HOSPITAL, AND INSTRUCTOR IN DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC MEDICAL SCHOOL.

Of all chronic conditions that a physician is called upon to treat, a running ear is frequently the most annoying, as well as the most perplexing that he has to deal with, and its cure often taxes the skill of the physician and the patience of the sufferer.

No part of the human anatomy in such a small space as the middle ear borders on so many vital structures as it does. Its proximity to the brain is such, that a suppurating process in the middle ear can readily destroy these separating bony wall and attack the brain. Anatomically and physiologically the middle ear is not comparable with any other part of the body. In health it is probably the most easily deranged part of the organism; and in disease it is often the most difficult one to treat.

A discharging ear is nearly always the sequel of an acute otitis media, and its having become chronic is usually owing to lack of proper attention in the acute stage of the disease. The natural inference is, that if all discharging ears were properly treated at the outset, they would never reach the point of chronicity at which they become destructive to the hearing and difficult to cure.

In seeking a cause for running ears, we have but to keep in mind the close relationship existing between the ear and the nose; and to remember that the nasal organ in civilized man is seldom in a healthy state. At once it becomes apparent that nearly every disease in the ear has its beginning in the nasal passages. The comparative frequency with which infants develop a running ear can be explained, on the ground that their Eustachian tubes are disproportionately shorter and more pervious than in adults, and that their mucous membranes secrete more actively. In fact, the lymphatic connection between the nose and the ear is so intimate in young children, that even a gastrointestinal or a respiratory trouble is usually accompanied by congestion in the middle ear.

The inception of most discharging ears can be traced to an acute fever, in the course of which the inflammatory exudate from the middle ear is unable to escape through the natural passage—the Eustachian tube—and is forced to make an artificial opening through the drum-head. Assume that a person is suffering from influenza or scarlet fever, and that all the mucous membranes in the head are inflamed and are actively secreting; the middle ear, in common with the other cavities in the head, throws off an abundance of inflammatory exudate, which, under ordinary circumstances, is drained off by the Eustachian tube and is carried to the nose. Sometimes, however, owing to a diseased condition in the nose, the Eustachian tube becomes obstructed, and the fluid from the middle ear is dammed up behind the barrier. When this occurs, the increasing exudate, not being able to escape, through the natural outlet, soon fills the middle ear, and finally, by its pressure, bursts the drum-head and escapes. In most instances the flow that follows the spontaneous rupture of the drum-head lasts but a short time, and

when the activity of the disease is expended, the discharge subsides and finally dries up altogether. An experience of this kind has been the portion of most every person, and yet they appear to be none the worse off for it. In a certain proportion of cases, however, the discharge shows no inclination to stop without assistance, but lapses into a chronic suppuration. When this occurs, it is quite evident that an underlying disorder is interfering with Nature in her effort to throw off the disease. The impediment may be a diseased condition in the nose or throat; or it may be due to the lowered vitality of the ear, or imperfect drainage, or a debilitated physical condition, or a constitutional disease, such as syphilis or tuberculosis.

In former years a running ear was regarded far too lightly; its serious nature was not generally recognized, and many sufferers were allowed to die from a resulting brain abscess, meningitis, or septicæmia, simply because the real source of these conditions was not known. Even to-day, in the course of acute fevers, such as typhoid fever or scarlet fever, many deaths can be traced to an unrecognized and untreated chronic abscess in the middle ear.

A discharging ear is so commonly met with, that most people regard it simply as an inconvenience, rather than as an actual disease that may destroy one of their most useful faculties and may even menace their life. It is an old and mistaken idea that a running ear is a natural outlet and conducive to health, and that to stop it would be dangerous. This superstition is still firmly fixed in the minds of a great many people, and it is responsible for the many serious consequences that so often follow from allowing a running ear to go untreated. The belief, no doubt owes its origin to the danger that is known to accompany the sudden stopping of a discharge that has been active for a long time. When such an arrest occurs, it is an indication that the escape of the secretion has been interfered with, and that unless an exit is speedily reëstablished, it will give rise to dangerous symptoms. Such an accident points to deficient drainage, and cannot happen if treatment is being directed to the abolition of the pus formation and not to the prevention of its escape.

While it is true that numerous persons with a discharging ear are not greatly inconvenienced and live to attain old age, it is probable that these people owe their immunity from annoyance to an excellent constitution, which has enabled them to enjoy good health, notwithstanding the discharge. At best, a running ear is an affliction that compromises a person's comfort at all times. It may at any time burst into renewed activity and become troublesome and even dangerous.

In view of the knowledge that running ears usually date from childhood, a discharge from a child's ear should be given prompt attention. This timely attention will prevent increasing deafness when the child grows older, and it will forstall the discomfort and danger that so often attend a running ear. The chronic catarrhal deafness in adult life is often but the sequel of a running ear in infancy, which was allowed to go untreated. Not infrequently parents are told that nothing can be done for the running ear of their child, and they are comforted with the statement that if Nature be permitted to take its course, the child will eventually outgrow the discharge. Experience has shown that such advice is erroneous and even injurious. A running ear is not self-limited by any means, and unless its activity is checked at the outset, the hearing may be partially or wholly sacrificed. The destructive process is carried on so insidiously that its progressiveness is not noticed until the deafness has become pronounced.

Because of its constant tendency toward deeper extension and erosion, a discharge of long standing is attended with more danger and is more difficult to cure than one of recent origin. For this reason and for the additional one that the vitality of the ear decreases with age, a running ear in an elderly person is more perilous to life than in a young person, but on the other hand, a discharging ear in a child is more injurious to the hearing.

Aside from the fact that three persons out of every hundred with a running ear die from causes that are directly traceable to that affection, it has a tendency, also, to shorten life by virtue of being a drain to the system and an impairment to the general health. This has become so apparent to life insurance companies, that many of them either refuse to insure persons with this defect or else they rate them as bad risks.

In the early stages of a suppurative otitis, merely the connective tissue in the middle ear is involved, and the secretion comes from the unhealthy granular surface that has replaced the normal mucous membrane. In many instances the disease confines itself to the soft parts alone and does not extend to the bone. In the event that the secretion is very abundant and unable to escape readily, it exerts a pressure in the middle ear that interferes with the blood supply of the ossicles, and causes them also to become diseased. The disease attacks first those bones, the nutrition of which is poor, or the position of which in the ear is such that they are exposed to direct contact with the pus. The long process of the incus is usually the starting point of this necrosis, the bone next to become diseased being the malleus, the head of which is readily eroded by the destructive action of the pus. Rarely does the stapes or the inner wall of the middle ear become affected, which is indeed fortunate, for otherwise the facial nerve and the internal ear would be implicated more frequently than they are. Even though the oval and the round windows remain bathed in pus for years a chronic suppuration seldom finds its way into the labyrinth.

It seems unnecessary to mention that the drum-head is perforated in all middle-ear discharges. There may be one or more openings in the drum-head, which may range in size from a pin point to a pea; or even to the loss of the entire drum-head, as is sometimes seen after scarlet fever. Multiple perforations are generally indicative of tuberculosis and are usually incurable. What we generally see is a single hole in the lower part of the drum-head directly behind the umbo. The discharge from a perforation in the lower part of the drum-head is more amenable to treatment than that from an opening higher up, because the latter almost invariably points to necrosis of the ossicles. This is especially true of a hole in the upper posterior quadrant of the drum-head, for this area is directly over the stapedo-incudal articulation, and the aperture affords an exit for the pus as it travels down the long process of the incus. Above the short process of the malleus is a section of the drum-head that is seen with difficulty, but which has an important bearing in middle-ear suppurations. This is Shrapnell's membrane, or the membrana flaccida, which covers the attic of the middle ear, wherein lie the head of the malleus and the body of the incus. An opening in Shrapnell's membrane is indicative of necrosis of the ossicles, and a discharge from this source is often intractable and ceases only when the diseased bone has been removed.

Although a perforation in the drum-head is ordinarily attended with diminished hearing, this is not always the case. Occasionally the entire drum-head

is wanting, and all the ossicles excepting the stapes are destroyed, and still the hearing remains good and the ear is dry. A hole in Shrapnell's membrane impairs the hearing very little, because in most of these cases the middle ear proper is shut off from the attic by a scar tissue and the disease is confined to the attic alone.

The quantity of secretion that escapes from a discharging ear varies greatly, and in a measure is influenced by the age of the patient and by the location and extent of the disease. Because of the activity of the gland-life in infancy, the discharge from a child's ear is usually more copious than in an adult ear. In many instances the flow is intermittent and recurs only at certain times; in other instances the discharge is so slight that it hardens as soon as it becomes exposed to the air, and it is then often mistaken for hard wax.

All running ears can be classified under one of two heads, granular and bony, according to the source of the discharge. In the former the secretion comes from the unhealthy granular surface that has replaced the epithelial lining of the middle ear. This discharge is mucopurulent, bland and unirritating, and like most catarrhal secretions, it is odorless and not very destructive. On the other hand, the suppuration arising from diseased bone is very injurious in its action; its virulency usually being commensurate with its chronicity. This discharge is acrid and irritating, and besides being ill-smelling and profuse, it favors the development of fungus in the ear and erodes the canal as it escapes. The presence of diseased bone in the middle ear is shown by a long-continued and fetid discharge, which contains crumbs of diseased bone; by rapidly recurring granulations and polyps; by hyperostosis of the canal wall; by swelling of the neighboring glands, and by the discovery of diseased bone with the aid of the attic probe.

In uncomplicated suppurations the disease is confined to the middle ear alone and the resulting secretion escapes freely into the auditory canal. Occasionally, however, the exit of the pus is interfered with, and the flow is diverted to the mastoid cells. In the healthy ear the passage between the mastoid antrum and the middle ear is very small, and in a running ear it is still further narrowed by swollen mucous membrane, granulations, or cholesteatomatous masses. If pus should find its way into the mastoid cells of such an ear, it might not be able to escape through this narrowed opening, in which case it would attack the mastoid cells in the effort to find a vent, and set up a mastoid suppuration.

The treatment of running ears has within the past few years undergone marked changes, and to-day is based on pathological knowledge and clinical analysis. The object of the treatment is to stop the discharge; to improve the hearing and to abate the discomfort and danger incident to the discharge. To effect these ends, a thorough knowledge of the anatomy and physiology of the organs of hearing is needful; together with an intelligent comprehension of their relations with the nose and throat.

To stop a discharge suddenly is not our purpose; there are many ways of doing this, but the condition of the ear is not generally improved thereby, and there are many disadvantages, and even dangers attendant on this procedure. What we should aim to do is to bring about the gradual diminution of the secretion and its ultimate cessation. We must remember that we are dealing with a pus-secreting cavity, and we must be guided by the same surgical principles and follow the same surgical methods as are incumbent on us to follow when dealing with a chronic abscess in any other part of the body. This implies the strict observance of cleanliness; the establishment of free drainage and the stimulation of the diseased area to healthy reaction. With these rules constantly in mind, it is not difficult to institute a rational method of treatment, whereby most discharges can be cured or else greatly lessened without surgical intervention.

One of the most essential points in the treatment of every running ear is to ascertain the direct cause of the disease. Not infrequently a discharge fails to yield to treatment simply because of some disorder in the nose or throat, that keeps up an irritation in the ear, and when these passages have been restored to their healthy state, the flow ceases without further attention.

Astringents, when properly used, are of considerable service and seldom fail to lessen a discharge. It is best to begin with weak solutions, increasing their strength as soon as a tolerance for them is acquired, or else changing them if they fail to diminish the flow. The astringents that have given me the best results are a solution of silver nitrate, grains 5 to 80 to the ounce; zinc chloride, grains 2 to 20; carbolic acid, grains 10 to 120; formalin, grains 5 to 40, and tincture of iodine, grains 5 to 60. Insufflations of alum, tannin, aristol, and nosophen are useful in selected cases. Active granulations are best destroyed by applications of chromic acid; while polyps are best removed by the ring curette. If the hole in the drum-head is too small for the free escape of the secretion, it should be enlarged in the downward direction.

The indiscriminate syringing of suppurating ears is now generally and certainly very justly condemned. In certain cases irrigations are advantageous, but in certain others they do positive harm. Few patients can use the ear syringe properly; they leave behind more fluid than they displace, and the moisture, by acting as a poultice, encourages the discharge and keeps the drum-head sodden and open. Most running ears can be satisfactorily cleansed if the patient will blow the secretion out of the middle ear by the Valsalva method, and then wipe it dry with cotton wound on a tooth-pick.

Should it be desirable to have the patient irrigate the ear, a solution of bichloride of mercury 1 to 5000, or a solution of permanganate of potassium, 1 to 1000, makes an excellent cleansing fluid. If the syringing is not agreeable, and is attended with dizziness and faintness, it should be discontinued. The discomfort is due, most likely, to a large hole in the drum-head, which exposes the stapes to the direct and forcible impact of the stream of water.

The best ear-drops for the patient's home use are a twenty-per-cent. alcoholic solution of boracic acid. Powder should never be used by patients to blow into the ear; they are apt to blow in too much, and it may become caked and obstruct the flow of the discharge.

Ordinarily it is not justifiable to operate upon a discharging ear until the milder methods of treatment have been tried and we have been convinced that conservative measures are unavailing. If the discharge persists, it is quite evident that it comes from diseased bone; the removal of which is requisite to effect a cure. Two operations have been devised for this purpose. One consists in removing what remains of the necrosed ossicles, together with scraping away the diseased tissue in the middle ear. This operation can be done quickly and with little shock, and being done through the canal it leaves no visible wound, and the patient is not invalided for more than a few days. This curetting operation should usually be done before resorting to the more dangerous and difficult external operation, in which

the opening is made behind the ear and the mastoid cells, the attic and the middle ear are thrown into one large open space. The curetting operation will usually effect a cure if the ossicles alone are diseased and the walls of the middle ear are but slightly involved, but if the necrosis is extensive and includes the bony tympanic ring and the neighboring bone, it usually becomes necessary to perform the Stacke or external operation.

NEURALGIA DUE TO DENTAL IRRITATION.

By WILLIAM J. LEDERER, D.D.S.,

Instructor of Oral Surgery at the New York School of Clinical Medicine; Former Demonstrator in Operative Dentistry at the New York College of Dentistry.

Neuralgia due to dental irritation, or dental neuralgia, is a paroxysmal pain caused by some abnormal condition of the teeth.

It may be local, diffuse, or reflected, according to the localization of the pain. We may have a painful spot, the whole area of nerve distribution may be involved, or the pain may be reflected to other nerves.

If we consider the anatomy of the trigeminus, we find that it is not only the largest of the cranial nerves, but its area of distribution is also widely spread, the nerve supplying sensation to the teeth and also being the motor nerve of the muscles of mastication. The trigeminus gives off the ophthalmic and superior and inferior maxillary divisions, each dividing into smaller branches, supplying the eyes, nose, ears, forehead, and scalp, the upper and lower lips, gums, tongue, and teeth.

A few ramifications of the maxillary branches arborize with the ophthalmic division and also with the facial and hypoglossal nerves. The intimate relationship its points of origin bear to the points of origin of the 6th, 7th, 8th, 9th, 10th, 11th, and 12th cranial nerves in the floor of the fourth ventricle, explains some of the reflex neuroses, which frequently are the result of dental irritation. The whole is a most wonderful mechanism constructed most intricately, and a disturbance anywhere along its course, no matter how slight, may involve any part or the whole area supplied by its branches.

The causes of dental neuralgia, from a dental point of view, are many, but like many other diseases it has predisposing factors. Anything that lowers the resistance of the system will modify the conditions resulting from dental irritation, and anæmia, syphilis, and especially gout and rheumatism predispose to neuralgia.

The exciting causes may be divided into those that are easily recognizable as: acute and chronic periodontitis; acute and chronic pulpitis; sensitive dentine, caries, pyorrhœa alveolaris, foreign bodies in the gum, alveoli, or pulp chamber, and atrophy of the gum.

There are other conditions, which are not so easily recognized but found only by careful exploration and differential diagnosis, and are exostosis, impacted teeth, and pulp nodules.

The first named conditions are easily recognized, and the neuralgia will usually disappear with the removal of the cause, provided the predisposing factors are not overlooked.

The difficult conditions to relieve are those which take their origin from the second named causes, the difficulty not lying in the treatment, but in the recognition of the cause.

If a patient presents with a neuralgia, whose etiology is doubtful, and it is suspected to be of dental origin, I have adopted a method of examination which often has proven valuable in determining the cause of the malady.

First. Each tooth is explored carefully, especial attention being paid to the gingival border and the general condition of the gum, as to tone. Each condition met with is recorded on an examination blank. The condition of the roots as to free exposures is carefully noted.

Second. Each tooth is carefully tested as to its sensitiveness to heat and cold, by means of the hot air syringe, and cold water.

Third. If no lesion has been found each tooth is examined as to its translucency with the electric mouth lamp, a valuable means of determining pulp changes.

Fourth. Each tooth is carefully percussed, which proves valuable to determine pericemental changes.

Fifth. Each tooth is tested with the electrical current as to its sensitiveness; this will frequently disclose pulp lesions, which otherwise remain obscure until much further advanced. The combination of these methods of examination, as a rule, will often disclose dental lesion, which, if one or the other method is employed alone, will escape the examiner.

Another feature of the examination should be a close questioning as to the systemic condition of the patient, so as to bring out any predisposing factors that might be present; and the dentist should, if necessary, communicate with the patient's physician. This is very important, as frequently success or failure will hinge on this point. Also the patient's occupation should be inquired into, as this frequently influences the constitutional condition.

The pathology of neuralgia of this type is somewhat obscure. Some investigators claim not to have found any structural change in the nerve tissue; others claim that the axis cylinder undergoes a modification; others, again, hold that the nerve tissue itself does not become altered, but that the small blood-vessels accompanying them do change, the connective-tissue elements in them undergoing an increase. It seems not improbable that this may account for the almost incurable cases of neuralgia in persons in middle life, brought on by a peripheral irritation, as a defective tooth, and which, even after the exciting cause is removed, do not abate. The paroxysms are relieved for a time by internal medication, but temporarily only. It may be a type of fibroid induration attacking the blood-vessels which are then unable to nourish the nerve tissue properly, the latter then undergoing some change that has not been demonstrated.

The prognosis of dental neuralgia is favorable unless it is associated with other conditions, as malaria or syphilis, when it assumes the infective type; it then ceases to be a true dental neuralgia and passes out of the hands of the dentist.

To treat dental neuralgia successfully, discretion and forethought are necessary. The mere mechanical removal of the cause will sometimes not be sufficient, but the constitutional condition of the patient must be considered. If the patient is anæmic, iron, in a suitable form, should be administered. If the patient shows a general debility, a good tonic, composed of iron, strychnine, arsenic and, perhaps, the hypophosphites, should be given. In cases of uric acid diathesis, lithia will be indicated and patients of this class are frequently subject to severe dental neuralgia, brought on by exposed roots. Excessive deposits of tartar are also found in some of these patients with gouty diathesis. Sometimes, especially in patients subject to pyorrhœa alveolaris (Rigg's disease), the diet should be paid some attention to—that is, coffee should be omitted entirely, and stimulants partaken of very moderately, if at all. The administration of the

iodides has proven successful in this condition, in my limited experience.

Patients with a malarial history can be benefited a great deal by the administration of quinine. This should be continued for a short time even after the paroxysms of pain have ceased. The two last named conditions, viz., the gouty diathesis and malaria, should always be looked into very carefully.

The exciting cause must, of course, be removed. If this is periodontitis, we should remove all irritants, such as tartar, and apply a counterirritant, such as tincture of iodine, tincture of aconite root and chloroform in equal parts, or paint the gum with cantharidal collodion. Constitutional treatment consists of the administration of a mild cathartic and bromides, or a mixture of quinine sulphate 3 ss, aromatic sulphuric acid 3 ii, and elixir of calisaya bark 3 xiv, in tablespoonful doses. I have used the coal-tar preparations combined with codeine and sometimes also with quinine with good results. A hot foot-bath will also prove beneficial. If there is an elevation of temperature I find a combination of one of the coal-tar antipyretics with quinine and Dover's powder, 3 gr. each, very useful. Also hot application to the face will prove of value at times. If the pulp is decomposing it should be removed and the roots treated antiseptically.

If sensitive dentine is the cause of the neuralgia, we are usually told to cauterize the sensitive spot with chloride of zinc in the front and nitrate of silver in the back of the mouth. However, I have found the vegetable astringents, like tannic acid, to act better; they seem to penetrate better than the other agents. I use the glycerite of tannin, to which enough tannic acid is added to make a fairly stiff paste. The secretions of the mouth should be rendered alkaline.

If caries is present, it is hardly necessary to mention the treatment. The recognition of the cause is sufficient. The presence of pyorrhœa alveolaris is also a subject that needs no further comment here. If the disease is the cause of neuralgia, it must, of course, be properly treated. In cases of true pyorrhœa I always prescribe iodide of potassium, and so far have had good results with it.

Foreign bodies in the gums or alveoli are frequently overlooked, and they may be the cause of reflex neuralgia. Pieces of toothpick, particles of lead or of other insoluble substances, as pieces of oyster shell, or minute particles of charcoal (which should not be used as a dentifrice, as it is insoluble in the oral secretions), or anything that acts as a foreign body and causes irritation, should be removed.

Injuries produced during tooth extraction, as fracture of the alveolus, may become factors in subsequent neuralgia. There is one condition met with occasionally that proves puzzling. People who have had their teeth extracted after some time become subject to a neuralgia. Gross calls this "neuralgia of the edentulous." This condition is met with more frequently in the upper than in the lower jaw, and is more prevalent among women than men. No doubt it is due to some injury of the fine nerve filaments. Gross ascribes it to compression of minute nerves, distributed through the wasted alveolar process, in consequence of the encroachment of osseous matter upon the walls of the canals in which these nerves are enclosed. The treatment consists in the removal of the affected alveolar process with sharp-edged bone forceps.

Atrophy of the gums, leaving the roots free and sensitive, which often causes persistent neuralgia, is best treated with the glycerite of tannin paste mentioned before. In these cases I give quinine, sometimes combined with iron and arsenic, also nux vomica, with good results. Sometimes acetanilide will do good service—in fact, some prefer it to quinine in neuralgia and periodontitis. Harlan gives acetanilide gr. viii in simple syrup and whiskey, one-half to be taken at once, the other half in five hours; Shoemaker gives acetanilide and lupuline, equal parts, in 10-grain doses. I use some of the coal-tar derivatives in combination with codeine or Dover's powder, with or without quinine—sometimes quinine alone, and have obtained satisfactory results.

Exostosis or hypercementosis is sometimes the initial cause of a dental neuralgia. It is ushered in with an uneasy feeling in the tooth affected, soon supplanted by a gnawing sensation, which at times takes on a neuralgic character. Some authorities claim that this condition can be reduced by the early administration of large doses of potassium iodide, and the local use of tincture of iodine. If the condition is advanced, the extraction of the tooth is the only remedy. This, however, is all well and good if the diagnosis of exostosis has been established, which is not always easy. Percussion of the tooth will sometimes disclose it, sometimes not. In cases of doubt, *x*-ray examination of the jaw will throw light upon the affection in more than one sense of the word.

Impacted teeth are also at times the cause of neuralgia, and if certain teeth are missing, which ought to have erupted according to the patient's age, an *x*-ray examination will facilitate the diagnosis. Once this is established, it is easy to obtain relief. The teeth most often producing these conditions are the wisdom teeth, and those situated in the vicinity of the antrum of Highmore. Pulp nodules or pulp stones are accretions of lime salts in the pulp of a tooth, which may be the cause of severe pain of a darting, shooting character. The removal of the pulp will put an end to the pain.

In many cases odontalgia is not a symptom of the malady, but the pain is reflected to another part. These cases are the ones that prove most puzzling, for the patient does not apply to the dentist for help, but goes to the family physician, who, lacking the dental training, does not always recognize the dental cause, but treats the case symptomatically, and the patient finds but temporary relief. Many interesting cases could be cited of various neuralgic affections in which the dental cause was obscure, and not determined until the oral specialist saw the patient. I shall mention but one that came to me recently. Miss S., æt. twenty-five, was referred to me by her family physician to see if I could account for a cervicobrachial neuralgia of the left side. I examined her mouth carefully, and found about a dozen teeth carious. On testing them with heat and cold, I found several with dying pulps. Her left lower wisdom tooth was badly broken down, and I extracted it with a negative result. The other teeth were dressed, and codeine was prescribed. Both without result, but as soon as a pulpitis of the second lower molar was reduced, her neuralgia, from which she had suffered four months, left her permanently. This case is reported simply to show the importance of a careful oral examination in all cases of neuralgia, the etiology of which is doubtful.

THE PHYSIOLOGY OF HUNGER.

By Dr. AXEL EMIL GIBSON,
LOS ANGELES, CAL.

THE majority of mankind associate the idea of hunger with the idea of poverty, want and suffering, and turn away from its contemplation with feelings of horror and disgust. Nevertheless, hunger, though representing the negative side of life, is as necessary a factor in evolutionary growth as is the food by which it is dispelled. Indeed, it might even be said that more than once this dreaded phantom has served as a prompter or incentive for individual efforts toward the attainment of fame and fortune.

Hunger, whether it be for bread or fame, is ever found to be a universal driving power, impelling the entities to an unfoldment and exertion of their slumbering powers. Hence it may be said that in a measure hunger lies at the base of evolutionary growth, and that civilization is deeper in debt to empty stomachs than to full ones.

Hunger is a sensation arising in the consciousness of the individual whenever the physiological balance between waste and repair is broken. Or perhaps more definitely, hunger, *i.e.* normal hunger, is the demand of nature made on consciousness for a replenishment of material to meet the needs accruing from a constantly proceeding expenditure in the vegetative life-process of individual existence whenever new fuel is needed.

As long as the individual adjusts his appetite to the suggestions of this faithful watcher, his physiological economy shows excellent results. The robust health of primitive man, his strength and endurance in the life-struggle, render sufficient testimony as to the promptness and triumphant intelligence exhibited by old mother hunger in the performance of her dietary administrations.

But imprudent man, as his sense-life grows stronger and wider, frequently thinks he can dispense with her services and indulge in the eating and drinking of whatever his fancy may suggest without waiting for the old monitor to give the proper signal. Thus interfered with, the function of hunger gradually loses its accuracy, becomes fitful and unreliable, and often clamors for supply for which the physiological conditions of the system indicate no need.

This opens up the reign of terror in which the individual swears allegiance to the tyranny of a corrupt and morbid appetite. Having discarded his servant hunger from his household, he elects Craving for his master, submitting himself to all the hardship and distress incident to lawless rulership. Chased like a madman from gratification to gratification, from candy stores and cafés to saloons and cigar stands, he spends the most and the best of his time and energy in administering to unnatural and unreal demands.

Meanwhile the *metabolism*—the assimilation and absorption of the body—is plunged into more and more distressing conditions of disorder and breakdown. Constructed on the principle of a furnace, the body in order to transform its nourishment into heat and energy requires for a proper combustion an adequate access to oxygen. And as in the case of a furnace an overcharge of fuel shuts off the supply of oxygen and thereby causes the fire to smolder, so in a similar way the flow and exchange of vital energy in the body is suppressed to a minimum when the individual overloads his digestive apparatus with food. If we are desirous of keeping our bodies at the highest mark of perfection and power we must refrain from choking the "fires of life" by pouring into our physiological furnace an excess of all kinds of combustible or incombustible material. In place of burning with the clear, lambent flame of perfect health and vigor, the "fires" under such management will turn into smoking, smoldering ash-heaps, productive of neither heat nor energy.

Then there is another danger which the individual in his present exposure must guard against. Enslaved by his tyrannous appetite, he has weakened his power of discernment, and as a consequence commits the fatal mistake of separating into halves and fragments what nature has prepared and turned out as whole and integral compounds. Not satisfied with the perfect combination of proteids, starch and fat, which the grain in its natural integrity presents, man in his unreason, by sifting the flour ruptures this integrity and thus disturbs the balance of nature's constructive processes.

The maintenance of life and health requires of the individual not only to *eat* but to *eat rightly*. In the metabolism of our body is found a condition known as the "nitrogen equilibrium" which means that within a given period of time the system has taken up an amount of nitrogenous food equal to the same amount of nitrogen used up and eliminated during a similar length of time. Hence a shortage in the assets of this vital economy will—if protracted—unavoidably lead to bodily decline and ruin.

Starch and fat generate heat and energy, while proteids (nitrogenous foodstuffs) supply material for the upbuilding and repair of tissue. Hence it becomes at once apparent that a protracted deficiency in the nitrogen supply means a breaking up of structural tissues—the muscles and bones of the body. As long as we heed Nature's instructions and use the foodstuffs in their simple natural combination, the problem of striking the "physiological balance" is easily solved; but the flour-sifting process separates the nitrogenous elements from the starchy, leaving us the latter wherewith to carry on the repair of our bones and muscles.

The same abnormal conditions are introduced in extracting and condensing sugar and salts. If we limited our use of these condiments to the extent they prevail in the fruit, grain, and vegetable, the balance of physiological waste and repair would be easily maintained. But by extracting the sugar from the vegetable—and the salt from the mineral kingdom, and introducing them as fundamental ingredients in our diet, we inaugurate abnormal processes of physiological activity, which means that we supplant the unity and integrity of nature's foodstuffs, with the diversity and imposition of an artificial and unwarranted separation.

The effects of this interruption of nature's methods is manifest in a host of metabolic disorders, of which the most formidable are those that come within the group of liver and kidney derangements.

Dr. Paul Bert, the famous French physiologist, has experimentally demonstrated that a dog fed exclusively on water will sustain life longer than a dog fed on bread of sifted flour. And the reason is evident: for water, which in itself contains a large percentage of life-supporting elements, has the power to maintain the metabolic balance of the dog, and enable him successfully to defy dissolution for quite a number of days. On the other hand, the dog put on the white bread diet, by his exclusive feeding on starch subjects his liver to a formidable strain, with no access to proteids for the repair of its used-up tissue. Hence in this case dissolution is actually hastened.

Dr. Robins, in his equally fascinating and instructive report of the Italian starvation-artist Succi's

forty days fasting, sheds much light on the subject of hunger. The progressive dissolution of structural tissues in the body during the fast is portrayed with scientific insight and accuracy. Step by step we are made to witness the physiological changes which in forty days reduced a well-formed and well-fed man to a tottering skeleton.

First 10 days' loss of weight amounted to 16 pounds.
" 20 " " " " " " 22 "
" 30 " " " " " " 28 "
" 40 " " " " " " 34 "

Total loss of body weight during the forty days' fast amounting to 26.55 per cent.

The progress of structural breakdown in starving subjects is registered in the elimination of *urea*—a nitrogen compound. For nitrogen, as we know, is taken into the body in the form of proteid, and deposited there in structural tissue. From this it follows that the elimination of nitrogen (represented in the urea) corresponds to the amount of bodily tissue used up during the corresponding length of time.

The amount of nitrogen which a healthy subject daily eliminates in the form of urea amounts to 3.5 grains for every pound of body weight. During Succi's first week of fasting he eliminated 3.04 grains per twenty-four hours; second week, 2.12 grains; third week, 1.66 grains. The fifth week the amount of urea rose to 1.8 grains, and the last four days to 2.10 grains.

This rise of elimination of urea toward the end of the fast marks the danger point of starvation—the second stage of "autophagy," or self-consumption. Having entered this stage the starvation is speedily approaching its fatal termination.

During the first stage of autophagy the subject feeds on his "circulatory proteids" (proteids suspended in the circulation and not yet "fixed" as structural tissue), *i.e.* the stored-up fats, sugar, albumin, glycogen, and adipose substances present in the body. The result of this consumption, though accompanied by a speedy loss of weight, is by no means fatal to the life of the individual. It is first when the bodily reserve funds are used up that the real danger threatens. The attack on the supporting tissues—the structural framework of the body—is of short duration. The breakdown and dissolution follow rapidly.

It is extremely interesting to compare the different degrees in which the different tissues are attacked and consumed in the course of a protracted starvation. Dr. Voit of Leipsic starved a cat for thirteen days, all the while carefully comparing and studying the changes taking place in the body. Thus, after thirteen days' starvation the cat had lost of

Bone	13.9	per cent.

Hunger is a nervous act. When the stomach has run empty its motion ceases, and the nerve terminations in the gastric walls, stimulated by the accumulated secretions of the gastric glands, send irritations to spinal cord and brain per pneumogastric nerve. This irritation is interpreted by the individual self-consciousness in terms of hunger, the latter varying in degree and intensity according to the intensity with which consciousness responds to the gastric stimulation. Hence the difference in strength of appetite and hunger in individuals of normal health is to be found in the nervous rather than in the digestive system; in the state of consciousness rather than in the state of physiology. Persons whose minds are engaged in schemes and projects of general interest ignore the pleasures of the table, while others again, whose minds are constantly absorbed in matters of personal comforts and gratifications feel the stress of not only strong but also morbid appetites. For true hunger, *i.e.* hunger as a physiological and normal process, in contradistinction to craving, which is a pathological or morbid hunger—is possible only after the consciousness of the individual has become aroused to the desirability of some gustatory act. Then the sluices to the secretory glands are flung open. The streams of gastric juice thus turned out over the interior walls of the stomach, stimulate the nerve-endings of the gastric nerve-plexus, which, being in communication with the brain and spinal cord, send a storm of reflexes to these centers, and thereby give rise to the emergence in consciousness of the sensation called hunger.

Thus for the sensation of normal hunger three physiological factors must be brought into activity: an empty stomach, an intact nerve connection from the gastric nerve-endings to the brain, and the concentration of consciousness on the gastric nerve-reports.

Thus the individual consciousness, by forcing the flow of gastric secretion, gives rise to the sensation of hunger. This fact readily explains why the sight, smell, or even the mere thought of savory food may create hunger—or, let us rather say, craving. As a case in point, reference may be made to one of Dr. DuBois-Raymond's latest reports in the *Archiv für Physiologie*, in which he relates an experiment with a dog whose stomach was connected with the exterior of the body through a fistula. A piece of meat held before his eyes caused a stream of gastric juice to flow out from the open fistula, thus demonstrating that the consciousness of the dog, and not the presence of food in his stomach, constituted the primary cause for the gastric secretion.

Applying this fact to the human individual, we are entitled to the conclusion that the sensation of hunger can be modified by mental effort. By promptly refusing to entertain the mind with thoughts and images of food and its relish, the gastric secretion will receive no stimulation, and hence the hunger be kept in abeyance. The "posthumous notations" of Antonio Viterbi—a Corsican lawyer—who, in the year 1821, was sentenced to death for some political reasons, furnish some very valuable arguments in favor of this view. In order to escape the death on the scaffold, for which he had an uncontrollable aversion, he resorted to death by starvation; and while awaiting a slowly approaching dissolution, took notes of the rise and fall of the feelings coursing through his consciousness,

From these notes we learn that on the third day of his death-fast the sensation of hunger disappeared. His head was clear, his thoughts sharp and lucid, and his eyesight extraordinarily keen. As the days went by, he felt the coming and going of sensations of thirst, but not of hunger. His consciousness remained alert and rational to the last. On the eighteenth day of his self-imposed starvation, he died. Neither thirst nor hunger had seriously annoyed him, and his last moments were calm and painless.

The calm intelligence and full realization with which Antonio Viterbi approached his fate, naturally held his thoughts and imagination away from representations of food. Hence the reflexes transmitted from the gastric nerve-endings to the brain

failed to elicit a conscious response. Hence no flow of gastric juice, and no sensation of hunger.

The same physiological principle is manifested in the behavior of demented and hysterical persons, whose minds being busy with subjective images of fright and horror, have been found to starve for weeks without ever making known any sensation of hunger.

On the other hand, if we inquire into the mental conditions of starving sailors, straying travelers, and other unfortunates who have been forced to face starvation with their bodies in full health, and their minds bound with chains of torturing fascination to the imagery of a riotous appetite, we will find that their sufferings have been truly indescribable. Like a Tantalus in the tale, who, surrounded by all the sumptuous viands of a highly wrought and morbid imagination, which he found himself unable to seize and to enjoy, so these unfortunates, with their gastric juice flooding the walls of their stomach, and with storms of irritating impulses rushing through their brain, have suffered untold agonies of hunger and thirst. In most cases of this kind the victims lose their reason before they lose their lives.

By the strength of these arguments we are entitled to the conviction that there is a power resident in every individual, enabling him to control and subdue, more or less successfully, his morbid cravings for food and drinks. The secret of breaking, a habit or a passion lies in the simple rule: hands off! Keep the mind off the enticing subject. Refuse promptly the idea of its gratification by removing the image from the field of consciousness. The undue secretions of the gastric glands will soon cease and with them the morbid cravings.

A study of the physiology of hunger may thus furnish us a powerful lever in the upbuilding of character and manhood. Indeed, the only real value to be found in the study of any science, philosophy, or religion lies in the bearing such a study may have on the elevation and purification of the thoughts and motives of men.

Congenital Dilatation of the Colon.—The following case is reported by Valentine Levi: In making a *résumé* of the prominent symptoms in this case we find: (1) Enlargement of the abdomen; (2) obstinate constipation; (3) diastasis of the recti; (4) tympanites replaced at times by dulness; (5) dilatation and downward displacement of the stomach and transverse colon; (6) visible peristalsis; and (7) some emaciation. There are two points in particular that this case brings out that have not been mentioned previously, in this condition. First is the separation of the recti muscles, admitting it to be congenital, or could it not be an important factor in causing the dilatation of the colon? Second, how can we account for the movable dulness in this case, there being no ascites present? The author can only ascribe it to the presence of fæces in the lower part and gas in the upper part of the intestines. As the intestines have a greater range of motility, due to the marked relaxation of the abdominal walls, they are more easily able to follow the laws of gravitation with the change of position of the patient, though limited, certainly, by their mesenteric attachments. The left flank remained flat in either the upright or dorsal positions; now, if we consider the attachments of the colon, we will see that its range of motion, with the exception of the ascending colon, is more restricted than that of the rest of the intestines. We must remember, too, that the descending colon is one of the most common sites for fecal impaction.—*Annals of Gynecology and Pediatry.*

Vaginal Cæsarean Section.—Ruhl has performed this operation nineteen times, and points out the necessity for one step which is not usually emphasized. This is that the cervix should be bluntly dilated as much as possible before beginning the incision. If this is not done the cervix after the sutures are laid will often be even tighter than before and retention of the lochia is sure to occur. Preliminary dilatation also renders a less extensive incision of the anterior uterine wall sufficient for extraction, and therefore fewer sutures need be placed. Another point of importance is that the proper cellular plane be followed in dissecting up the bladder, as much hemorrhage can be avoided in this way. Cases in which a former vaginifixation has been done are extremely difficult, and to avoid injury to the bladder the old line of incision must be followed closely. The parts are also very inelastic in these cases, so that a long incision through the anterior uterine wall is necessary.—*Centralblatt für Gynäkologie*, No. 2, 1904.

Alopecia Congenita Familiaris.—Kraus reports four cases of alopecia congenita familiaris in the children of one family. The first patient, who died at the age of one and one-half years, was born with abundant black hair, which it lost after the first bath, it is said. The other cases were in the second and third children. The parents were supplied with normal growth of hair, and no pathological condition could be found among relations. Another patient was a girl, aged three and one-half years. She had long, black hair at birth, which began to fall out at the fifth week, and at about the ninth week there was total alopecia. No pathological appearances nor disease of the scalp were apparent. Patient was otherwise normal and strong; nails, teeth, eyelids, lashes, etc., all normal. (No hairs on body, not even lanugo.) Another case was that of a brother of the first patient, one and one-half years old, who had, with exception of a strip of finger width in the median line, a normal supply of hair. Loss of hair began in seventh week. No eyebrows or lashes present at birth, as in the other case, but these appeared later (in both cases). No hairs present on any part of the body, even no lanugo. Kraus excised a portion of the scalp from the girl in region of occiput, at the line of demarcation of growth of the hair on the neck; from the boy he took a portion from behind the ear. Upon examination of the specimens no hair or papillæ could be found anywhere. Two kinds of hair follicle were distinguished. A marked deviation from the normal condition was present in the sebaceous glands and errectores pilorum. Both presented marked transposition. The sebaceous glands were not situated at the side of the follicles, the axis forming an angle with the longitudinal axis, as is usually the case, but lay parallel to the longitudinal axis of the follicle. They also differed in shape and were not pouch-shaped, but appeared as ducts with slight enlargement at the bottom. As a result the errectores pilorum did not touch the fundus of the glands, but passed to one side without coming in contact with them. On the contrary, it was found that the sweat glands were fully developed. His deductions are that histological discoveries prove that the alopecia was due to a disturbance of the fetal change of hair. Concerning the relationship of alopecia congenita with disturbances of keratinization, Bettmann claimed that in none of the cases hitherto examined could hypotrichotic changes as those found in Bonnet's goat be demonstrated. While, on the contrary, Audry recently reported a case in which the scalp presented marked disturbances of keratinization, as well as other peculiarities. In a child, aged four, who was well developed, but born bald, fine hairs first began to return at the end of first year. Audry assumes that the scalp was affected by congenital keratosis, which prevented normal development of the hairs by penetrating into the hair sheaths.—*Archiv für Dermatologie.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

STATE LAWS FOR THE PREVENTION OF TYPHOID FEVER.

THE widespread prevalence of typhoid fever in many sections of the United States, due to the pollution of drinking water, and the lack of suitable State Laws for the prevention of such contamination, is a serious reflection on the intelligence and common sense of the different municipalities concerned. Whenever a serious epidemic of the fever occurs, it is generally too late to stop its initiatory ravages, although no time may be lost in tracing the sources of infection. In a large majority of instances no danger is suspected until the mischief is done.

It is safe to say that no means of preventing disease are so much neglected as those of proper inspection of water supplies, and no greater damage done to the health of municipalities than the neglect to apply them. It requires no argument to prove that the entire system of water supply and sewage disposal requires radical reconstruction. The time is past when mere municipalities should be held responsible for water contamination in their own jurisdiction. Not only should each State take the matter in hand and compel uniform regulations, but with streams passing through other States there should be a system of interstate inspection under the charge of a national bureau. The necessities for the latter measure are shown in many sections having a common supply and a common outlet. The contamination of Lake Champlain by the outputs of many of the factories on its shore is a notable instance in point. The local health authorities are so powerless in the matter of applying restrictions to the intolerable nuisance that the War Department has been compelled to interfere and insist that the various mill owners shall cease the pollution so bitterly complained of.

It is a matter of congratulation that the State of New York has taken the initiative in the matter of controlling the sewage system of the commonwealth, and of thus preventing the contamination of water supplies. Although the system is by no means a perfect one, due to the present impossibilities of immediately altering old and long-established methods of drainage, there is in it a reasonable guarantee that the newer provisions instilled will effectually check the propagation of the time-honored but effete methods of drainage, and will eventually substitute more desirable and practical ones.

The present law provides that "No person, corporation, or municipality shall place or cause to be placed, or discharge or cause to be discharged into any of the waters of this State, unless the same shall have been permitted by the State Commissioner of Health, any sewage, garbage, offal, dead animal, dead fish, dead bird or part thereof, or any decomposable or putrescible matter of any kind or any substance, chemical or otherwise, containing the same in quantities injurious to the public health, or any refuse or waste matter, either solid or liquid, in quantities injurious to the public health, from any shop, factory, mill or industrial establishment; unless express permission to do so shall have been first given in writing by the State Commissioner of Health as provided in this article, except as hereinafter provided. But this act shall not prevent the discharge of sewage from any public sewer system owned and maintained by a municipality or the discharge of refuse or waste matter from any shop, factory, mill, or industrial establishment, provided such sewer system was in operation and was discharging sewage, or such shop, factory, mill, or industrial establishment was in operation and discharging refuse or waste matter, into any of the waters of this State at or prior to the time of the passage of this act, nor to any extension or modification of such shop, factory, mill or industrial establishment or reconstruction thereof, provided the refuse or waste matter discharged therefrom is not materially changed or increased; but this exception shall not permit any increase in the discharge of such sewage, nor shall it permit the discharge of sewage from a sewer system which shall be extended, modified, or reconstructed subsequent to the passage of this act."

The power is invested in the State Health Commissioner to grant or revoke permission for every new sewage system throughout the State, and to compel by penalty and fine the enforcement of the statutory regulations. His is very properly the central bureau of control, while the local authorities are in turn held responsible for any lack of supervision of water supplies and sewage outlets in their respective districts. This is as it should be, and gives the executive officer a proper and practical control of the entire system. From such a point of view, for instance, there are very many possibilities of preventing epidemics which have not existed before when the local boards acted independently of each other. That they have been incapable heretofore of meeting emergencies has been proven in the epidemic of typhoid fever at Ithaca a year ago, and in the more recent outbreak at Watertown. It is now only a matter of detail to insist that all cases of typhoid fever in any district of the State shall be immediately and directly reported to the central bureau at Albany, when prompt investigations as to the origin of an epidemic can be made and proper means instituted to prevent the dissemination of infection. The same precautions, would, of course, apply to any similar water-borne disease. It is lamentable to think, however, that with all these desirable features this admirable law is practically a dead letter, for the want of funds to make its provisions effective. That such is the case is no fault of the State Health Commissioner, as he has repeatedly applied for a suitable appropriation to carry on this part of his work. He still asks for $20,000 to that end. In no better way could the Legislature minister to the needs of public health than by granting the request. New York has shown a most commendable example to other States in having such a law on its statute

books, and it only remains for her now to prove its practical utility by her ability to enforce its provisions.

SHALL THE GENERAL PRACTITIONER DIVIDE FEES WITH THE CONSULTANT?

THE interest manifested by various correspondents in the question of division of fees between general practitioner and consultant proves, in some sense, the prevalence of the custom, and the need of some well-defined ethical principles that should govern both of the parties concerned.

One of the main troubles that would reasonably explain the condition of affairs is the necessarily keen competition for business among all classes of medical men, growing out of the overcrowded state of the profession. Under such circumstances there is always a temptation to cross lines in the struggle and skirmish for individual advantages. This has been the state of affairs more particularly since specialism has separated itself from general practice.

There is no doubt that the general business of the family physician has suffered in consequence of this innovation, but he is nevertheless made the better practitioner in the end, in benefiting directly and indirectly by the work of pioneers in all the special branches. The specialist, on the other hand, must curtail his work within proper limits, and confine himself entirely to the particular branch of his specialty. The conscientious general practitioner should always be ready to advise consultation with an expert, when such service is demanded, and when any operation requiring special skill in its execution is necessary he should temporarily resign the direct care of his patient to the specialist. On the other hand, the operator, as soon as he has rendered the particular service required of him, should deliver the patient to the former regular attendant. There should be no question as to the relative duties and privileges of either party in the transaction. This is the proper ethical line of division between general medicine and specialism, and needs no argument to prove the equity of its assumption. When this much is admitted, we may be perhaps better prepared than otherwise to discuss the question of division of fees between the regular attendant and consultant.

It is plain to be seen that as each has his place in the case, each should be paid for what he actually does. As the patient is the payer for both, he should be the one to be satisfied that the fees are properly apportioned. This is a purely business matter that can always be discussed on the broad principle of justice and right to all, as it places the giver and receiver in direct and proper contact with each other.

If the contrary is the case by any collusion of the recipients there is an implied reason for concealing dishonest practices. The operation or expert advice has its distinct price and should go entirely to the one who performs the special service, otherwise he is cheated of his just due. No middle man has a right to levy toll or commission, as he is in no way entitled to the profits of another's skill. If the consultant charges an extra amount to cover the commission he is plainly obtaining money under false pretences and defrauding a patient who trusts to his common honesty. The giver and receiver of the extra money are thus equally guilty of fraud. The fact is evident enough in there being something that must not be explained on the basis of an honorable understanding.

Another element of fraud in the business is the absence of unbiassed judgment in the selection of the consultant. Herein the patient is the direct and innocent sufferer. It is not the man who is best fitted to perform the operation or to consult on the case, but the one who will "divide up" most handsomely. Thus the patient, by the intervention of an interested agent, is deprived of the services of the self-respecting man whom he would be glad to choose for himself.

Taking, then, all the main facts into account in considering the question of sharing fees there can be no question as to the conclusions to be drawn. The practice is wrong from any point of view, and the man who gives or takes under the circumstances, is unjust to himself, his patient, and his profession.

CONCERNING THE PROPOSED INTRODUCTION OF WHIPPING INTO THE PUBLIC SCHOOLS.

DURING the Dark Ages, when retributive ideas of punishment were all but universal, the infliction of physical pain as a penalty for crimes, even the most trivial, was a well-established principle of jurisprudence. Then it was that the thumb-screw, the rack, and the fagot achieved their outrageous missions, secure of the countenance of Church and State alike. When, later, science began to penetrate the dark corners of men's prejudices, there was a notable relaxation of the rigors of the judicial code; but the final banishment of torture was only achieved after the barbed sarcasm of Voltaire had pricked the public conscience.

Since those days it is safe to say that, in civilized communities, at least, the ingenious deviltry of the torturer is in disgrace.

Now and again, however, the evidence is afforded that there are still those among us who, under a more euphemistic designation, would still set up torture on its gruesome pedestal. The horrible atrocities of the lynchers are an extreme illustration; while the proposition, recently put forward, to again confer upon the rod its baneful prerogative in the public schools, is a minor symptom of the same tendency.

It is against this subordinate sway of savagery—this proposition to rule little children by terror and by pain—that the MEDICAL RECORD most emphatically protests. The whip inspires terror of itself and not of the crime; its physical effects, quite aside from the pain engendered, are bad and may be deplorable; its moral influence is shameful and degrading. Nothing is more certain than that belaboring the buttocks—whether with strap, stick, or fist—as a rule—causes inordinate stimulation of the reflex activities of the cord, particularly of its lower parts. Hence the invoking of the whip by weakened debauchees to stimulate their diminished powers—a practice almost as old as history.

How, in view of such facts, guardians and parents came to adopt such a mode of punishing the young is difficult to determine. Lack of knowledge of possible consequences, is perhaps the most charitable explanation. Commenting on the physical and moral dangers of flagellation, Krafft-Erbing observes:

"*Libido sexualis* may also be induced by stimulation of the gluteal region (castigation, whipping).

"This fact is not unimportant for the under

standing of certain pathological manifestations. It sometimes happens that in boys the first excitation of the sexual instinct is caused by spanking, and they are thus incited to masturbation. This should be remembered by those who have the care of children.

"On account of the dangers to which this form of punishing children gives rise, it would be better if parents, teachers, and nurses were to avoid it entirely."

Further, and quite as important, there are the moral evils of whipping. To cuff, cudgel, and maltreat a child is to foster the rebellion of an outraged self-respect. Boys of hardy make, thus cruelly mishandled, are easily converted into liars and bullies; while in those of more sensitive organization, the imagination is dulled, ambition discouraged, and the spirit broken beyond all mending. And finally, to crown the scheme of fatuous ignorance and cruelty, there are the truant children, feeble-minded and epileptic, not a few of them, upon whom all a-quiver and irresponsible, the blind fury of the whip descends in an ecstacy of remorseless vengeance.

The lash has had its day. It is too late now to officially countenance the infliction of pain, either as a punishment for offences committed by children or adults. In all schools, and particularly in the public schools, there is a considerable proportion of backward, deficient, and feeble-minded children. These should be carefully segregated, observed, and instructed in accordance with their special needs. For the rest, let there be rewards, humane penalties, drill—military, perhaps; and last, but far from least, an abundance and variety of sports, not only for purely physical reasons, but as vents for that mischief that still lingers with us as a fantastic heritage of our simian ancestry. Nothing that is permanently good can be brought about by force or brutality. The infliction of pain is never an argument in favor of right or justice.

NON-NEPHRITIC RENAL ALBUMINURIA.

It is a somewhat unfortunate custom to apply the qualification "idiopathic" or "essential" to various disorders of obscure origin, and we doubt if anything is gained by employing the term "functional" instead. Disease, as an aberrant manifestation of life, never arises spontaneously, any more than does life itself. The causes may not always be obvious, but none the less they should not be ignored to the extent of failing to make careful search in every case for them. Increased knowledge of etiology makes for advance in prevention.

Among disorders whose causation at times eludes recognition is albuminuria, which under such circumstances is by some designated "physiological." As, however, albumin, in appreciable amount, is not a constituent of normal urine, its presence can never be considered physiological. Therefore, it would be better, for the present at least, to adopt the suggestion of Dr. Samuel West (*Lancet*, January 16, 1904, p. 143) and describe such a condition as "albuminuria in the apparently healthy." From a considerable experience and a careful study of the subject, Dr. West expresses the opinion that albuminuria may occur as a transitory symptom in persons who, except for this symptom, may be judged to be perfectly healthy, as they appear to be so at the time and remain so. Such albuminuria may occur also in persons who, although they appear at the time to be healthy, develop signs of disease subsequently. It is difficult to distinguish at a given time between those that will remain well and those that will not. It is difficult also to exclude with certainty many of the pathological causes to which the albuminuria might be due. In other words, although there may be no proof that these causes are present, there is equally no proof that they are absent, and in some cases the result shows that they were not absent. Speaking generally, the larger the amount of albumin in the urine, and the longer it persists, the greater is the probability that some permanent disease is present. Continued observation of cases of the kind under consideration shows that so-called physiological albuminuria appreciably increases the risk of life, and that this risk grows rapidly with every year of age after thirty years. Dr. West finally formulates the general conclusion that functional albuminuria is never, strictly speaking, physiological at all, but that it is, on the contrary, always pathological, though not necessarily renal.

An Act Defining Optometry, and Regulating the Practice Thereof.

An act has been introduced into the Senate of the State of New York, to legalize the "practice of optometry." The bill in question is speciously framed and is apt to lead astray those not possessing a knowledge of the matter. The reasons against licensing opticians are many and obvious. A large number of these merely pose as opticians, being absolutely incompetent and far more likely to do harm than good. When the fact is considered that a fair knowledge of the eye is only gained after many years of earnest and assiduous study, it will be understood that few opticians possess the necessary qualifications to lay claim to the title of expert. Again it would be manifestly unjust to place physicians upon the same plane as opticians. A medical man has to undertake a course of studies to prepare him for the work of treating diseases. It would, indeed, be hard, after having completed his appointed period of study, and after having demonstrated by passing examinations that he is qualified to care for the sick and physically defective, if he should find himself obliged to compete upon more or less equal terms, with others who have received little or no preparation. There can be no doubt that medical laws are necessary for the protection of the general public, but if the door is to be thrown open to those who have had practically no training, of what use are such laws. If opticians are licensed why not osteopaths, and others of the same genus. When the thin edge of the wedge has been once introduced, no one can forsee the end. The medical profession, therefore, should fight vigorously against any such infringement of their privileges as contemplated in the proposed legislation for opticians. If any person chooses to trust the care of his vision to an ordinary optician he has a constitutional right of exercising such a privilege, but to sanction the work of the optician by legal enactment is altogether quite another matter.

Opposition to Tuberculosis Hospitals.—An ordinance forbidding the opening of hospitals for consumptives within the city limits has been adopted at Los Angeles.

Professional or Registered Nurses as Witnesses.

An act has been introduced into the Assembly of the State of New York bearing upon the testamentary privileges of physicians and professional nurses. The first section of the amended act reads as follows: "Physicians or professional or registered nurses not to disclose professional information. A person duly authorized to practise physic or surgery, or a professional or registered nurse; shall not be allowed to disclose any information which he acquired in attending a patient, in a professional capacity, and which was necessary to enable him to act in that capacity. In the examination of physicians or professional or registered nurses as witnesses, it is enacted, that these may, upon a trial or examination, disclose any information as to the mental or physical condition of a patient who is deceased, which was acquired in attending such patient professionally, except confidential communications and such facts as would tend to disgrace the memory of the patient."

An act of the nature now before the New York State Legislature would seem to be somewhat superfluous. The fact is generally well recognized that a medical man must preserve a discreet silence with regard to any information he may receive from a patient. The same statement applies to a professional or registered nurse. The physician and the nurse alike have no business whatsoever with any matters outside their own province of work, and their ears should be deaf to extraneous subjects. With the physician, at least, it is a question of honor, and the man who failed to act up to the high level demanded of the medical profession would be rightly contemned by his brethren. If it is deemed necessary to seal the lips of professional and registered nurses by law, then let it be so. At the same time, it would seem that there is no valid necessity for such a measure, as the courts very generally recognize the physician's privilege in such matters.

The Prevention of Consumption.

Dr. Alfred Hillier has recently published a short volume with the above title. Dr. Hillier is secretary of the British National Association for the prevention of this disease, and has for many years made a close study of the malady. Some two years ago the author had in mind the writing of such a book, but thinking that Professor Koch was better equipped for the purpose, urged him to undertake the work. Koch, however, was unable to do so, but promised to revise and comment on it, and in other ways to give his aid. The book is written in popular form, and shows that "Tuberculosis may be cured, can be avoided, and ought to be prevented." It is stated that "Deaths from tuberculosis in England and Wales are estimated to amount yearly to 60,000, and in the rest of Europe to a million. In England one-half of the deaths between the ages of twenty-five and thirty-five are caused by phthisis. In the United States and Canada the proportion is about the same. In the larger centers of population in Europe the highest mortality is in Moscow, St. Petersburg, and Vienna, and the lowest in Amsterdam, London, Naples, and Buenos Ayres.

According to Dr. Hillier, the oldest writers were aware that consumption spread by contagion. The magistrates of Florence, in 1754, enforced certain regulations for the disinfection of the rooms in which there had been patients suffering from tuberculosis. In Rome, at a later period, somewhat similar rules were carried out. At the time when Italian art was at its height, consumption exercised influence upon art. Dr. Hillier writes that Bolticelli's favorite model died of consumption, and also says that the modern Rosetti had a consumptive for a model.

Concerning the spread of tuberculosis, Dr. Hillier is of the opinion that there can be no doubt as to the manner in which it gains an entrance into the human body. "The paths of invasion" are several. Heredity was formerly believed to be an important factor in the dissemination of tuberculosis. This idea has now been abandoned. The most common mode of entrance is by inhalation. Another form may "occasionally occur in kissing or in using spoons or plates which have been previously used by tuberculous patients." Inhalation, however, is probably the chief source of the propagation of consumption. The main danger arises from the sputum of those who are consumptive mixed with the substances thrown out in the act of spitting the tubercle bacillus. If it falls on the floor it may become dry, and may be inhaled and convey tuberculosis to those predisposed to the disease.

Dr. Hillier is a firm believer in open-air treatment of consumption, and favors generally the modern methods of endeavoring to prevent the malady. He also advocates the compulsory notification of cases of consumption to the health authorities, the establishment of sanatoria under medical supervision, and the supression of spitting in all covered places.

Although, to an American physician, the contents of Dr. Hillier's book will not be novel, yet it is well written, and presents facts in an attractive manner. The only part of the volume with which many readers will not be in agreement, is that which deals with human and bovine tuberculosis. Dr. Hillier is a disciple of Koch, and with him believes "that human and bovine tuberculosis are different forms of the disease." If read by the British public Dr. Hillier's work should act as a popular educator, which, indeed, was the author's idea in writing it.

A New Protozoon.

Leishmann, in the *British Medical Journal*, May 30, 1903, published a paper in which he put forward the hypothesis that a fever which occurs in India, known as Dum-dum fever was a form of trypanosomiasis. He further suggested that cases of Dum-dum fever and Kala-azar should be carefully examined for trypanosomes microscopically by centrifuging a quantity of blood, or by inoculation into monkeys.

The *Journal of the British Royal Army Medical Corps*, January, comments editorially on this matter, and says that Leishman's paper brought out a letter in the *British Medical Journal*, July 11, 1903 from Captain Donovan, I. M. S., in which he stated that he had also noted these bodies in smear preparations taken from three cases of natives who were thought to have died of chronic malaria At a later date, Donovan, finding identical bodies in the pulp and blood of a patient who came under his charge, sent smear preparations to Major Ronald Ross, Liverpool, and to Dr. Laveran in Paris. Dr Laveran concluded, from an examination of these specimens, that the bodies belonged to the genus Piroplasma, not to Trypanosoma, and proposed for them the name Piroplasma Donovani.

Ross, at the same time published papers in the *British Medical Journal*, November 14 and 28, 1903 on this subject.

He did not agree with either Leishmann or Laveran, but thought these bodies probably belong

to a new species of sporozoa, and proposed Leishmania as a fitting generic appellation.

The *British Army Medical Journal*, February, above referred to, publishes a translation of the investigations of Laveran and Mesnil regarding this protozoon, and thinks, from a consideration of their paper, and especially from the figure given therein, that Leishmann's bodies do show a marked likeness to the piroplasmata.

More convincing evidence, however, must be forthcoming ere any decided opinion on the matter is given.

An interesting fact in connection with piroplasmata is mentioned in the *British Army Medical Journal*, that these protozoa cause diseases of domestic animals in all parts of the world, as a rule by means of ticks, and that it is the progeny of the tick that has this infective power. "If then," the editorial in question goes on to remark, "Dum-dum fever is proved to be caused by a piroplasma, the insect-carrier should be looked for, and it is the ticks which should be viewed with suspicion."

It is not stated whether Dum-dum fever, which appears to be a form of dysentery, occurs outside India, but the probability is that it is not unknown in other parts of Asia, and perhaps in all tropical countries.

There may be a chance of investigating this point in the Philippine Islands, where, if such be the case, the opportunities for prosecuting research are exceptionally good.

Anti-malarial Campaign.

Now that the anti-malarial campaign will soon be in full swing, and the festive mosquito soon issue from his hibernating quarters, prepared for a test of the survival of the fittest, it is not without interest to consider efforts which have been successfully put forth toward the prevention of malaria in countries where this disease is much more prevalent than in our own. We refer to the recent report of Captain S. P. James, I. M. S., on the anti-malarial operations at Mian Mir in 1901 and 1902. These operations were conducted along two lines: (1) The destruction of mosquitos; (2) the destruction of malarial parasites in infected individuals, or the removal of these persons from the vicinity of the operations. The destruction of mosquito was attempted in four ways: (1) Smoothing the sides of water courses and freeing them from grasses and weeds; (2) bricking one course which ran through the artillery lines; (3) cleaning out and thoroughly drying water courses once in ten days—this was discontinued on account of the expense; (4) oiling irrigation courses and pools and filling in the latter where practicable. In order to carry out properly these measures constant work was necessary, as even a short interruption allows the former conditions to become reëstablished. For the destruction of malarial parasites in infected individuals, quinine was relied upon. This was given in sufficient doses to bring about the desired result. Infected persons who could not be so treated were removed from the region of the operations. The results of the work were chiefly estimated by the prevalence of malaria among the troops. The annual rate per 1,000 in Mian Mir is 663, but in the year 1902 this was reduced to 269. This shows a vast improvement, and the question arises as to which of the above methods was the most concerned in bringing it about. Captain James believes that it was chiefly due to the removal of infected individuals or their treatment by quinine. Investigations showed that the efforts put forth for the destruction of mosquitos had but little effect, as only a slight impression was made upon the number of these insects. Moreover, it is very expensive.

In our own country the warfare against mosquitos has been waged with considerable energy. It is as yet too early to say what ultimate results will be obtained, but it is probable that the methods hitherto used will be abandoned, both on account of expense and non-effectiveness. On the other hand, in most parts of this country malaria is not a disease of sufficient gravity to warrant the isolation of those infected with the malarial parasite. In those regions, however, where pernicious malaria abounds, measures for the isolation of those infected until the parasites are no longer present in the general blood circulation, deserve careful consideration. Generally speaking, in this country the prevention of malaria is very far from being on a satisfactory basis, and it is apparent that the disease must be attacked in a different manner than has hitherto been attempted.

Dysentery or Typhoid Fever?

In the *Bulletin of the Ayer Clinical Laboratory* of the Pennsylvania Hospital, October, 1903, Dr. Louis M. Warfield reports a case as acute dysentery, which is suggestive. The patient, a male forty-eight years of age, was admitted to the hospital on April 17, 1903. He complained of diarrhœa of three days' duration and gave a history of having been unable to work for three weeks previously, although he had not been confined to bed. During this period he had suffered from headache, giddiness, and vomiting. On admission blood was present in the stools, but the number of these did not exceed twelve in twenty-four hours. The tongue was coated and dry. The temperature was 101° F. In two days it reached normal, at which point it permanently remained. The urine contained albumin and casts and the total leucocyte count was 3100. On April 18 the Widal test was tried and found positive. The stools became copious and consisted wholly of mucus and blood. They contained no amœbæ but rod-shaped bacilli in fair numbers. From these stools a rod-shaped bacillus was isolated which by morphological, agglutination, and cultural tests was proven to be the dysentery bacillus of the acid-producing type. On May 1 the patient was discharged cured.

The interest in this case attaches to the fact that the blood of the patient agglutinated both dysentery and typhoid bacilli. Furthermore that the total leucocyte count was decidedly hyponormal while the clinical history was not unsuggestive of ambulating typhoid fever. It is to be regretted that an attempt was not made to isolate typhoid bacilli from the fæces and urine. In the want of such evidence it cannot, of course, be positively held that the case was one of typhoid fever, but it is very probable that it was such. The dysenteric symptoms were in all likelihood due to an added infection with the dysentery bacillus, but the opinion that the case was essentially one of typhoid fever cannot be discounted. The positive Widal reaction, the total hypoleucocytosis, and the previous clinical history are strong evidence in support of this view. It is this class of cases from which the most is to be feared in the dissemination of typhoid fever—that is, cases of typhoid fever which have not been recognized, and in which no effort is made to prevent the dissemination of typhoid bacilli by the fæces and urine. When such cases come under medical supervision they should be most carefully studied and every effort made to ascertain whether or not they are sources of danger. Until such measures are carefully instituted we may be sure that typhoid fever will continue to be an endemic disease of large proportions.

Measures looking toward safeguarding the avenues of infection of typhoid fever—such as water and milk supplies—are valuable, and should everywhere be put into operation, but we shall never strike at the root of the matter until more attention is paid to the destruction of the bacillus as it leaves the bodies of those suffering with or convalescent from the disease.

New York State Hospital for the Care of Crippled and Deformed Children.

The third annual report—for the year 1903—of this institution has recently been published. During the thirty-four months that the hospital had been in existence, with accommodation for only 25 patients, 52 patients have been received and treated during that period. Of this total, 33, or 63.46 per cent., were cases of tuberculous disease of the joints. Of the whole number treated 27 have been discharged. Of these, 55.55 per cent. were cured and 44.45 per cent. discharged as more or less improved, many of them practically cured. 51.92 per cent. of the whole number treated have been discharged.

The average time of treatment of the 27 patients discharged since the hospital opened its doors on December 7, 1900, has been one year, 3.6 months, and of the patients who are now in the hospital, the average residence is one year, four months.

On the first of October, 1902, there were 25 patients in the hospital. During the year ending September 30, 1903, 12 new patients were admitted. Of the 37 treated during the year, 24 were boys and 13 were girls, and of this number, 12, or 32.43 per cent. of the whole number, were discharged. Seven of these twelve were cured, and five were so far relieved, that in the opinion of the attending medical men, ordinary home cure, is in all probability, all that is necessary to complete the cure.

The report states that there were at least three hundred and fifty applications for admission during the past year, while the hospital will only accommodate twelve patients. Various sites for a new hospital are now under consideration which, when completed will hold a much larger number of patients. A new building is urgently needed, and considering the usefulness of such an institution, funds should be forthcoming to provide adequate accommodation for as many crippled and deformed children as is possible. The small hospital at Tarrytown has done excellent work, a proof that with extended facilities the good effected will be proportionately greater.

Probable Mode of Infection by the Filaria Perstans.

Dr. H. Charlton Bastian, in a short article contributed to the *Lancet*, January 30, calls attention to the No. 3 report of the British Royal Society Sleeping Sickness Commission, written by Dr. Cuthbert Christy. In this report it is pointed out that the distribution of Filaria perstans in East Equatorial Africa corresponds almost exactly with the area of "distribution of the banana cultivation and clothed people." Christy says "Wherever the banana is growing in the districts I have examined, there is found the Filaria perstans. What is more, it would seem that where the banana is most luxuriant there the inhabitants are most infected. The converse of this is also clearly correct; that is, where the banana is scarce there the percentage of Filaria perstans is small; and where there is no banana there is no Filaria perstans." The uses to which the banana is put are thus referred to: "The banana when fully grown is peeled, boiled, or steamed in an earthenware pot. The leaves are used for plates and dishes, for thatching houses, for clothing, for matresses to sleep upon, for pipe stems and many other things. Dr. Bastian states that nematoids are frequently to be found in the roots, stems, and leaves of plants, and that they are known to be found in the roots, at least, of the banana as it grows in Eastern Australia. From his own experience with wheat, feverfew, and the cucumber, and from information received from Australia with regard to the banana Dr. Bastian reaches the conclusion that the nematoid in question really belongs to the genus Tylenchus. The modes in which the natives use the different parts of the banana would make it possible for them to be infected either (1) through the skin, or (2) through the alimentary canal. In short, Dr. Bastian takes exception to the view now held that Filaria perstans infects directly through the skin, but is strongly of the opinion that the worms termed Filaria perstans are of the genus Tylenchus and infect through the alimentary canal.

Care of the Insane.

Despite all argument to the contrary, it would seem to have been proved almost conclusively that the number of the insane is increasing throughout the world. That such is the case in highly civilized countries, admits of no doubt. Statistics, although by no means always to be relied upon, are on this point so definite that they must be regarded as, to a large extent, trustworthy. In Great Britain at the present time a great hue and cry is being raised with regard to the physical degeneration of the race, but as the *Hospital*, January 16, points out. there is a tendency to neglect the equally serious mental deterioration which is assuming alarming proportions. The following figures, taken from the last British census returns, will show that the alleged increase of insanity is no idle dream: In 1871 there were, in England and Wales, 69,019 insane persons In 1881, 84,503; in 1891, 97,383, and in 1901 132,654.

But while insanity is thus on the increase, better methods of treatment have progressed *pari passu* and the asylum is not, as was once the case, the living grave of the insane person. Mental affection are treated with no small measure of success, and the man who has suffered from temporary mental aberration, and who for his relief has spent some time in an asylum, is no longer regarded as a marked person nor is his future wholly spoiled by the occurrence.

The most notable feature of the *Hospital* article is its advocacy of the employment of female nurses in the care of the insane. In some districts of Great Britain this system has been followed with much success. According to the *Hospital*, the admission is made by those who have had the longest experience, both in this country and abroad, that female nursing is preferable for sick and infirm men, and it is also believed by many that the presence of women in asylum wards obviates proportionately to the number and influence those regrettable personal conflicts which tend to occur from time to time when insane men are wholly attended by individuals of their own sex. There are, undoubtedly, many cases of insanity in which women are better fitted as attendants than men. On the other hand, a large class of insane persons require male nurses, as female attendants would not, by reason of their inferior strength, be able to restrain them when violent. Perhaps the best plan would be to have in every asylum a certain number of female nurses who could take charge of those patients deemed suitable for such care by the physicians.

Ludwig's Angina.

Dr. Gwilym G. Davis of Philadelphia writes in the February number of the *American Journal of the Medical Sciences*, on a case of Ludwig's angina.

The patient had had a bad tooth in the lower jaw for some time. A week previously the neck began to swell, and later the swelling rapidly increased, until on admission he was only able to part the jaws less than a centimetre; the tongue was thick, and filled the mouth, and it was also pushed upward by the swelling on the floor of the mouth. The neck was enormously swollen, the swelling extending from the zygoma above to the clavicle and sternum below, and from the edge of the trapezius muscle on one side to beyond the median line on the other. He had stertorous breathing, difficulty in swallowing, and could only talk in a whisper. Under primary anæsthesia, an incision was made in the line of the ulterior edge of the sternomastoid muscle, and two rubber drainage tubes passed parallel to the jaw and brought out near the median line. Only a very small amount—a few drops—of pus was obtained. The temperature was 101° F.; pulse 120; respiration 24.

An incision was made some distance below the angle of the jaw, and as soon as the deep fascia was opened a closed hæmostat was pushed ahead into the tissues and opened. In this way two passages were tunneled upward to beneath the lower jaw; also two across the neck, one curving upward toward the jaw, and the other downward toward the clavicle and sternum. Drainage tubes were placed in each, but no distinct collection of pus was found. However, on the fifth day after operation the discharge of pus was more free, and the patient was taking solid food. He was dismissed on the tenth day, with the discharge almost stopped, and his general and local conditions excellent.

In his comments on the case Dr. Davis says "Some authors regard the disease as resembling erysipelas. This seems to me to be only so to a small extent. I believe it to be a distinctly local condition, propagated by traveling by direct continuity of tissue, and capable of being relieved by free opening of the infected area." In the case dealt with by Dr. Davis there was a direct causal relation between the diseased teeth and the onset of the inflammation. This fact, together with the prompt subsidence of both local and constitutional symptoms, as the result of local treatment alone, all point to the disease as being a distinct local infection, and not erysipelatous in character. Complete anæsthesia is dangerous in these cases, and the safest course would be to use local anæsthesia or none.

A Cystoscopic Jubilee.—It is proposed to send a congratulatory cablegram to Prof. Max Nitze of Berlin on March 9, the twenty-fifth anniversary of the first demonstration of the cystoscope by him. The cablegram will be as follows: "Prof. Max Nitze, Berlin: Your colleagues and pupils congratulate themselves and the profession on the twenty-fifth anniversary of the demonstration of the cystoscope. *Vivat magister!*" All who desire to add their signatures to this message of congratulation, are requested to send at once a copy of the signature, with the city of residence (written in one line of paper not over four inches broad) to Dr. Ferd. C. Valentine, 31 West Sixty-first street, New York. Those sending names are asked to forward at the same time twenty-five cents for each word of signature and address.

News of the Week.

A Graceful Recognition of Prof. Robert F. Weir's Long and Valuable Services.—At a recent meeting of the Faculty of the College of Physicians and Surgeons, the Medical Department of Columbia University in the city of New York, it was unanimously

Resolved, That this Faculty desires hereby to express its great appreciation of the eminent services rendered to his alma mater by Robert Fulton Weir, M.D., a graduate of this college in the class of 1859, and an officer of the said college for the past thirty-six years. Twenty years ago Dr. Weir was appointed Professor of Clinical Surgery, and ten years ago he was called as Professor of Surgery to the seat in the Faculty from which he has lately intimated his wish to retire.

Dr. Weir's distinguished career as a teacher has been coupled with a career no less distinguished as a private and a public practitioner of surgery. He was for twenty-seven years visiting surgeon to the New York Hospital, and he has held the same office at St. Luke's Hospital, the Bellevue Hospital, and the Roosevelt Hospital. His colleagues on each side of the Atlantic have borne witness to his high professional repute by electing him President of the New York Academy of Medicine, President of the American Surgical Association, and Honorary Fellow of the Royal College of Surgeons of London. Of Dr. Weir's colleagues in this Faculty many have enjoyed the benefit of his teaching, and all unite in this proffer of sincere respect and hearty thanks.

Resolved, That the foregoing resolution be entered at large in the minutes of this meeting, and that a copy thereof be engrossed, signed by the President of the University and by the other members of this Faculty, and presented to Dr. Weir.

Nicholas Murray Butler, Ph.D., L.L.D.
Jno. G. Curtis, M.D.
William T. Bull, M.D.
M. Allen Starr, M.D., L.L.D.
Geo. S. Huntington, M.D.
T. Mitchell Prudden, M.D.
Edwin B. Cragin, M.D.
Walter B. James, M.D.

The Sanitation of the Isthmus.—The Committee on Medical Legislation of the American Medical Association, consisting of Drs. C. A. L. Reed of Cincinnati, Wm. L. Rodman of Philadelphia, and Wm. H. Welch of Baltimore, has addressed a request to President Roosevelt urging *First:* That a representative of the medical profession be appointed as a member of the Panama Canal Commission; *Second:* That Colonel William C. Gorgas, Surgeon U. S. Army, be appointed to such position; *Third:* That the committee be given a personal hearing on this question before the commissioners are finally selected. In support of this request the committee "urges that, under both of the French administrations at the Isthmus, the engineering problems themselves, to the chagrin of the medical profession of the world, failed of accomplishment largely through the frightful mortality among officers and laborers consequent upon lack of authority on part of medical officers entrusted with the work of sanitation; that the same conditions of insalubrity exist now that existed then, and that, consequently, the sanitary problems are to be recognized as second in importance, if second at all, only to those connected with the engineering department. As a consequence, the committee, in furtherance of the principle established by the Congress, urges that the technical skill involved in the solution of medical and sanitary problems be likewise invested with highest administrative au-

thority through actual representation in the personnel of the commission. This committee begs to add that it recognizes, and in the recommendations herewith submitted has been governed by the fact that the commissioners, to carry out the objects of their official existence, must possess administrative ability of the highest order; and that no person, whatever his technical qualifications, ought to be appointed who does not possess personal integrity, a knowledge of men, familiarity with affairs, acquaintance with values, the faculty of organization and executive ability backed by courage, both of the highest order. These qualifications exist in the medical profession as well as out of it, and the committee is assured that they are to be found in eminent degree in Colonel Gorgas, whose appointment is hereby solicited at your hands."

A Reserve Medical Corps for the Army.—A bill is now before Congress providing for an increase in the medical corps of the army. In addition to the Surgeon-General with rank of Brigadier-General, there will be 16 colonels, 24 lieutenant-colonels, 110 majors, and 300 captains or first lieutenants. It further provides for a reserve corps of medical officers available for military service. To this end the President of the United States is authorized to issue commissions as first lieutenants therein to such graduates of reputable schools of medicine, citizens of the United States, as shall from time to time, on examination to be prescribed by the Secretary of War, be found physically, mentally, and morally qualified to hold such commissions, the person so commissioned to constitute and be known as the medical reserve corps. The commissions so given shall confer on the holders all the authority, rights, and privileges of commissioned officers of the like grade in the medical corps of the United States Army, except promotion, but only when called into active duty and during the period of such active duty. Officers of the medical reserve corps shall have rank in this corps according to date of their commissions therein, and when employed on active duty shall rank next below all other officers of like grade in the United States Army. Contract surgeons now in the military service, who receive the favorable recommendation of the Surgeon-General of the Army, shall be eligible for appointment in the reserve corps without further examination. In emergencies the Secretary of War may order officers of the medical reserve corps to active duty in the service of the United States, in such numbers as the public interests may require, and may continue such officers on such duty so long as their services are necessary. Officers of the reserve corps will be entitled to the pay and allowances of first lieutenants of the regular medical corps, with increase for length of service now allowed by law, income to be computed, however, only for time of actual duty. No officer of the medical reserve corps will be entitled to retirement or retirement pay; nor will he be entitled to pension except for physical disability incurred while in active duty, and in line of duty. This bill has received the approval of Secretary Taft, and will doubtless be passed by the Senate and House.

The Study of Leprosy.—The Board of Health of Hawaii some time ago formulated a plan for the systematic study of leprosy at the settlement of Molokai. The plan included a request for an appropriation from Congress for suitable provision for a bacteriological laboratory at the leper settlement, and for residences for investigators. The Territory of Hawaii would provide maintenance and assistance, and an invitation would be sent to the leading institutions and societies in the world which provide for original research into such subjects, to send capable investigators. Surgeon-General Wyman, in pursuance of the same object, has invited Dr. Charles B. Cooper of the Board of Health of Hawaii, Dr. J. F. Smith, secretary of the Superior Board of Health of San Juan, P. R., and Dr. J. C. Nolte of the State Board of Health of Louisiana to become members of a committee to undertake an exhaustive investigation and study of leprosy. This committee is to suggest lines of investigation to competent observers willing to undertake the work, and also to collate the results of experiments and observations made in connection with its work, and to report at suitable times on the progress of the work.

Centenarians and More.—Sophia Gab, probably the oldest woman in Chicago, died there last week. She was supposed to be 129 years old. Born a slave, she spent most of her life on a plantation near Richmond, Va. When released from slavery during the Civil War she was eighty-seven years old. A still more remarkable story of longevity is contained in the notice of the death of Noah Raby in New Brunswick, N. J., on March 1. It is asserted, with much circumstantiality, that he was born in Gates County, N. C., on April 1 (significant date!), 1772, so that had he lived one month longer he would have been 132 years old. He entered the United States Navy about as soon as the United States had a navy, and after serving for a number of years, was honorably discharged in 1809. He never married, but had smoked and chewed tobacco for 122 years, and had at one time been a heavy drinker.

For Superintendent of the State Hospital for Consumptives.—Only two of the five candidates passed the recent State Civil Service examination for the position of superintendent of the new State Hospital for Consumptives, to be located at Raybrook, in the Adirondacks. The successful candidates were Dr. John H. Prior of Buffalo, who is a member of the board of managers of the institution appointed by the Governor, and Dr. Frederick L. Hills of Binghampton. The salary of the position is to be $3,500 a year and maintenance. The three applicants who were unsuccessful on the examination passed the written test, but failed, it is said, in the practical part, which included the physical examination of patients and diagnosis of the disease.

Against Patent Medicine Portraits.—A bill has been introduced into the New York Assembly, the purport of which is to prohibit after May 31 next the publication by any newspaper or other public periodical except medical or surgical journals, of "any picture, device, or representation of one or more man, woman or child, or of the features or any part or parts of the human body in connection with or as part of any advertisement of any patented medicine, drug, or surgical instrument." We hope the bill will not pass, for we should miss the pictures of the hearty whole-souled gentleman who has lost and found his manhood, and of the sweet young thing whose bowels have been moved by something more tangible than compassion, and of the placid, white-haired octogenarian whose functions have been miraculously regulated by the vegetable compound of a lately deceased benefactress of her sex.

New York Antitoxin in Chicago.—A number of druggists, it is said, have applied to the director of the Chicago municipal laboratory for permission to handle the antitoxin secured by the city health department. They will sell the remedy at 75 cents for 1,000 units, $1.25 for 2,000 units, and $2.25 for 3,000 units. The Chicago Health Department has lately been getting its supply from the New York Board of Health, on the plea that the regular manufacturers charge too much. The question of propriety of the

New York Board of Health supplying Chicago with antitoxin for free distribution to the poor might be open to discussion, but there can be none concerning the impropriety of furnishing the druggists with the remedy for sale to the general public.

A Bill to Abolish the Officer of Coroner.—A bill has been introduced by Senator N. A. Elsberg into the New York State Senate providing for the abolishment of the office of coroner in New York City upon the expiration of the terms of office of the present coroners, and enacting a bureau of medical examiners in the department of health to exercise the powers and perform the duties now lodged with the coroners. The bill provides for one chief medical examiner, and other medical examiners not to exceed six for the borough of Manhattan, four for the borough of Brooklyn, and two each for the boroughs of the Bronx, Queens, and Richmond. These medical examiners are in the first instance to be appointed from the coroner's physicians in office when the change is made, and afterward from the eligible lists prepared by the Civil Service Commission.

Mt. Sinai Alumni Association.—The seventh annual reunion and dinner of the Associated Alumni of Mount Sinai Hospital was held at the rooms of the Freundschaft Society, Seventy-second Street and Park Avenue, on Wednesday, February 17, Dr. G. L. Brodhead presiding. The following officers were elected for the ensuing year: *President*, Dr. Edwin Sternberger; *Vice-President*, Dr. Charles Goodman; *Secretary*, Dr. Leo B. Meyer; *Treasurer*, Dr. Eugene H. Eising.

Junior Staff for Orange Hospital.—The work of the Orange Memorial Hospital has grown so rapidly that it has been found necessary to enlarge the corps of physicians and surgeons. In order to meet this contingency, the board of governors of the institution has appointed a junior staff, consisting of Dr. Douglas Aymar Cater, Dr. Edgar Calvin Seibert, Dr. Walter D. Dodge and Dr. Linn Emerson of Orange; Dr. A. W. Bingham, Dr. Stephen G. Lee and Dr. C. R. Neare of East Orange, and Dr. Richard D. Freeman and Dr. Henry A. Pulsford of South Orange. It will be the duty of these physicians to act as assistants to the senior staff, and in addition they will take charge of and develop special departments in the hospital.

The Jenkins Medical Association held its regular monthly meeting on Thursday evening, February 25, at the residence of Dr. Edward F. Brush, Mayor of Mount Vernon, N. Y. The paper of the evening, entitled "Scientific Infant Feeding," was read by Dr. H. D. Chapin of New York. After adjournment an elaborate banquet was served. Among those present were Drs. E. J. Harrington, Robert T. Howe, Henry Moffat, Jas. T. Gibson, A. M. Campbell, Edw. Duffy, F. W. Shipman, W. D. Granger, G. S. Mooney, O. L. Austin, E. M. Hermance, J. A. Knapp, A. C. Benedict, N. A. Warren, A. F. Currier, J. W. Bowden, and H. E. Smith, all of Westchester County, and Drs. H. D. Chapin and Wm. M. Leszynsky of New York.

Congressman Baker's Freak Bill.—Mr. Robert Baker, Representative in Congress from the Sixth New York District, writes us disclaiming all responsibility for the absurd bill, one provision of which—that, namely, establishing a department of public health—we quoted in a recent issue. The bill was introduced by him, he says, on request of Mr. Cowdon of Washington. Mr. Baker refuses to stand sponsor for it, for he writes that he is an individualist and is opposed to every form of paternalism in government.

Diphtheria on a Warship.—A telegram from San Juan, P. R., dated February 25, reports that an outbreak of diphtheria has occurred on board the United States training ship *Monongahela*. The entire crew has been ordered ashore, and the ship will be disinfected. Twenty-two cases of apprentices suffering from sore throats are under observation in the tents of the Marine Hospital.

Jubilee of the Class of '79, Coll. P. & S.—The twenty-fifth anniversary of the graduation of the class of '79 of the College of Physicians and Surgeons was observed by a dinner at the Hotel Manhattan last Saturday evening. There were ninety-nine members in the class, of whom about one-fourth are now dead. The president of the class, Dr. T. Dwight Palmer, is dead, but the secretary, Dr. William F. Wright of Manhattan, and the marshal, Dr. Everett J. McKnight of Hartford were present.

Reporting Cases of Contagious Disease.—Scarlet fever, measles, and diphtheria are prevailing to an unusual extent in this city now, and it is said that many cases occur that are not reported to the Board of Health. In order to jog the memories of those who forget to notify the Bureau of Contagious Diseases, the Health Commissioner has announced that the rules of the department are to be strictly enforced, and all physicians have been warned to report every contagious case that comes under their notice, or else suffer the penalty of a fine.

The Mount Sinai Hospital.—Preparatory to removal of the hospital to its new buildings at Fifth avenue and One Hundredth Street, the admission of patients at the old hospital has been discontinued. A reception will be held at the new buildings on the afternoon and evening of March 15 and 16. On the following Monday patients will be admitted to all departments.

New Hospital in Porto Rico.—The Presbyterian Hospital of San Juan was opened on February 27 with appropriate ceremonies. The hospital cost $20,000, which was raised in New York. Governor Hunt delivered an address.

Hospital Cars for Consumptives.—An innovation in train operation will soon be put into effect on the Santa Fé Railway, between Chicago and Kansas City, to Colorado and New Mexico health resorts, and to California points, over practically the entire system. This will consist in the running of hospital cars at intervals on through trains. These cars will be specially equipped, and no one except sick persons will be allowed to ride in them. At the same time consumptives will not be allowed to occupy seats or berths in the Pullman coaches. The care of consumptives has always been a burden to the railroads. After a berth has been occupied by a consumptive, it must remain unoccupied until the end of the run, when it is disinfected.

First-aid Material on Railways.—The Pennsylvania Railroad has ordered "first aid to the injured" boxes and stretchers to be carried on all baggage, mail, express, work, and wrecking trains. They will also be kept in yards and stations.

Dr. W. P. Northrup delivered the annual address before the J. C. Wilson Medical Society (composed of undergraduates and graduates) of Philadelphia on February 19. The subject was: "Joseph O'Dwyer, M.D.: His Methods of Work: The Measure of His Success: the Interest of Both to Young Graduates."

No Municipal Training School for Nurses in St. Louis.—The nurses for the City Hospital at St Louis are drawn from the St. Louis Training School, but recently an ordinance was introduced in the City Council asking for a municipal training school for

nurses. Only nurses recommended by the St. Louis Training School are accepted in the City Hospital, and this discrimination against outside schools has aroused considerable controversy. The ordinance introduced was intended to overcome this discrimination. Assistant Health Commissioner Francis and Dr. John Young Brown, Superintendent of the City Hospital, after a conference, decided that the present system is satisfactory, so the ordinance will be withdrawn.

Dr. Francis Delafield, who has been ill with lobar pneumonia for several days, is, his many friends will be pleased to know, doing well, and all indications point to an early recovery.

Dr. Frederick Peterson has sent to Governor Odell his resignation as a member of the State Commission in Lunacy. Dr. Peterson is president of the board. It is understood the resignation may not take effect for some time.

Typhoid Fever in West Virginia.—The health authorities of West Virginia are endeavoring to cope with a grave epidemic of typhoid fever in the mill district at Benwood. The disease is raging in the foreign settlement, and the Slavs are crowded so closely together and are so hard to deal with that the health department is totally unable to bring about sanitary conditions. Forty and fifty Slavs have been discovered sleeping in one small apartment, the beds being run on double time, the night force having possession during the day and the day mill hands coming in for the night.

Dr. H. J. Bogardus, for some time one of the surgeons to the New York Orthopedic Dispensary and Hospital, has been appointed surgeon to the orthopedic department recently established at Christ's Hospital, Jersey City.

Drs. Stella Stevens Bradford and N. Gilbert Seymour have been appointed by the trustees, Clinical Assistants to the Tuberculosis Clinic, Outpatient Department of Gouverneur Hospital.

Dr. H. J. Strack of Cincinnati was recently appointed District Physician for the Sixteenth Ward, to succeed Dr. Paul DeCourcy, resigned.

Measles Epidemic.—At the Home for the Friendless in Cincinnati fourteen of the twenty babies in the institution are suffering from measles. The disease was introduced by a child returned from the Cincinnati Hospital, which broke out with the disease three days after its arrival.

Gift of a Hospital.—James La Bouteaux, a wealthy farmer of Delaware County, Ind., has presented his county with $20,000 to build a county hospital, the only condition being that it be named for his deceased wife, Huldah La Bouteaux.

Dr. Ogden C. Ludlow, a valued member of the MEDICAL RECORD staff, has been suffering for some weeks from typhoid fever. The disease has been of comparatively mild form, and we are very glad to be able to announce that he is now practically out of danger.

Columbus Typhoid Epidemic.—The number of cases of typhoid fever in Columbus, Ohio, this winter has reached 1,500, with a death rate of 8½ per cent., 123 being the total number of deaths.

Kentucky Medical Bill Passed.—The House of Representatives at Frankfort, Ky., has passed a bill recognizing the regular school, also the Homœopathic, Eclectic, and Osteopathic Schools of Medicine on the State Board of Health and the State Board of Medical Examiners. The bill now goes to the Governor for approval.

Prize Essays on Tropical Diseases.—The prizes in the gift of the *Journal of Tropical Medicine* for essays on subjects connected with tropical diseases have been awarded as follows: The Belilios Prize of £10, for the best essay on "The System of Drainage and Sewerage (Domestic and Municipal) Best Suited for Tropical Climates," has been awarded to Major F. Smith and Captain J. W. Cornwall. The Lady MacGregor Prize of £10, for the best article on "A Critical Examination of the Practical Value of Antityphoid Inoculation," has been awarded to Major F. Smith. The Sivewright Prize, for the best essay on "Intestinal Affections in Warm Climates," was not awarded.

A Dinner to Dr. D. B. St. John Roosa.—On Tuesday evening a dinner was given at Delmonico's in honor of Dr. D. B. St. John Roosa and also to commemorate the inauguration of post-graduate medical instruction twenty-one years ago, with which Dr. Roosa has been so prominently identified.

The occasion was one long to be remembered by the large number of representative medical men present from this and other cities. Old and young practitioners who had not met for years gathered around the festive board and united in cheering and congratulating the recipient of the honors of the hour. When a loving cup was presented to Dr. Roosa by Dr. Andrew H. Smith on the part of the faculty of the Post-graduate Medical School, the entire audience arose and testified its appreciation of the sentiments which prompted the gift.

The toasts offered were also in keeping with the purposes of the gathering and in the main were confined to topics bearing on the progress and prospects of the higher medical education.

Dr. Wm. Osler of Johns Hopkins University presided, and in his usual felicitous manner made the introductory speech, taking for his subject the "general requirements of the medicine of the future." Among the things that had been already accomplished was the making a medical education a part of the University course, thus awakening the public to the need of higher medical education, also the establishing on a sound basis the National Medical and State Associations, and taking from the schools the former control of the profession. The duties now before the profession were to make places in the hospitals for the third and fourth-year students, and to establish schools for investigation in every medical department. He confidently believed that the time would come when there would be a merger in medical teaching, and that each of the smaller cities at least would have but one medical school instead of wasting time, money, and energies in striving to operate three or four weak and inefficient institutions. Interstate reciprocity was also a necessity, each State having a common standard of requirements for medical license.

Dr. Clarence J. Blake of Boston spoke on the "need of post-graduate instruction for the specialist," and the necessity for a high standard of requirements in these advanced branches of study

The "Need of Post-graduate Study for the Surgeon" was the subject treated by Dr. William J Mayo of Rochester, Minn. He gave a very interesting account of the progress of post-graduate study in the Northwest, and proved how much could be accomplished by singleness of purpose and earnestness of effort on the part of men determined to make the most of limited opportunities. The "need for increased endowment for medical institutions" was exhaustively discussed by Dr. W. W. Keen of Philadelphia. In a stirring address he graphically illustrated the mere commercial value of medical research by proving what had been accomplished in guaranteeing communities against smallpox, yellow fever, plague, cholera, and typhoid fever. "But a few years ago a single case of cholera down the bay meant millions

lost to your merchants. To-day a case does not create a ripple of excitement, because the community knows your medical men have these diseases by the throat.

"Our work in Cuba has been epoch-making, and the merchants from New Orleans to New York are reaping the benefits of this unselfish labor. To-day in India 100,000 persons a year are offered up on the altar of the plague, yet our work has diminished the susceptibility to that disease 77 per cent.; and we believe the day is coming when the plague, like yellow fever, will be wiped out."

Mr. William Potter of Philadelphia, as the only layman among the speakers, offered a graceful tribute to the unselfish labors of the profession in the matter of disease prevention and of the great value to the community of institutions for medical research. Then followed Dr. W. M. Polk, who spoke upon "civic pride in medical institutions", and convinced his hearers that no such condition existed as yet in New York and would not until the medical colleges arose to better opportunities for progressive usefulness. Lastly, Dr. Roosa gave a review of twenty-one years of post-graduate work, and concluded his address by a graceful and touching allusion to the kindly spirit that had actuated the gathering.

Obituary Notes.—Dr. WILLIAM RANKIN, Jr., for over thirty years a practising physician of Newark, N. J., died at his home in that city, on February 26, aged fifty-six years. He was a graduate of Rutgers College in 1868, and of the College of Physicians and Surgeons in this city in the class of 1871, and also studied in Vienna. He was for years on the visiting staff of the Newark Charitable Eye and Ear Infirmary, and Secretary of the old Newark Library Association, and a member of the American Ophthalmological Association, the American Otological Association, the New Jersey State Medical Society, and the Essex District Medical Society. A son and two daughters survive him.

Dr. GEORGE W. NEVILLE, a pioneer physician and preacher, and a Union leader in the days of border fighting, is dead at Bethel, Kan., aged eighty-two years. At the beginning of the Civil War he recruited the second battalion of Missouri State Militia, and in 1862, with one hundred recruits, he repulsed an attack upon Harrison Mills, Mo., by three hundred of Quantrell's guerillas.

Dr. MARCUS HENRY SLOSSON, one of Cincinnati's oldest physicians, died at his home in that city on February 22 at the age of eighty-five years. He was at one time Dean of the Pulte Medical College.

Dr. R. J. WILDING of Malone, N. Y., died suddenly on February 24, of heart disease, at the age of sixty-nine years. He was born in England and was a licentiate of Apothecaries' Hall, London, in 1856.

Dr. OTIS AVORY, ninety-six years old, without doubt the oldest practising dentist in the world, died on February 22 at Honesdale, Pa., where for more than half a century he had practised his profession. Probably the first dental diploma or certificate ever issued was given to Dr. Avery on December 6, 1833, by Dr. Ambler of this city. Six years later, in 1839, the first dental college in the world was established in Baltimore.

Dr. DAVID D. TOAL died at his home in this city on February 26, at the age of sixty-six years. He was born in Ireland, but was brought to this country when two years old. He was a graduate of the New York University Medical College in the class of 1867.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CONFISCATION AS A MEDICAL REFORM—THE VISION IN RHEUMATOID ARTHRITIS—CANCER AT THE THERAPEUTICAL SOCIETY—MR. BALFOUR—MEDICAL ATTACHES FOR THE WAR—ASYLUMS BOARD—ROYAL ARMY MEDICAL CORPS PARLIAMENT.

LONDON, February 12, 1904.

A MONTH ago I mentioned to you a proposal to confiscate the right of medical men to dispense. The suggestion seemed so absurd and was accompanied by such a monstrous provision penalizing men for using rights to obtain which they had expended much time and money that most people at first regarded it as a mad project undeserving of any serious attention. Nevertheless it has not been abandoned, and our branch of the British Medical Association is going to hold a discussion upon it. Meantime it has been talked about in some quarters, and the *Lancet* has uttered a mild but quite distinct disapproval and admitted correspondence showing the folly of the scheme.

There are some other instances of mischievous meddling by the so-called ethical committee of the association, but few such outrageous proposals as this—to fine a practitioner £100 the first time he dispenses his own prescription and exclude him from the register on a second offence against this proposed confiscation of his rights. It seems incredible that educated men in this century should make themselves responsible for such a project. Yet it would appear that a few consultants, with probably little to do and eaten up with the notion of their own importance and the dignity of their profession, have come to the conclusion that dispensing tends to degrade a doctor and diminish his social importance. Poor victims of their self-conceit! Can they really suppose that they would improve their position by dishonestly depriving others of their rights? In many cases such deprivation would mean ruin, and if the advocates of the scheme do not know this they should be ashamed of their ignorant meddling with things which they do not understand.

As I have said before, there is no fear that Parliament will entertain such a scheme of confiscation for no benefit whatever to the public, and only the persistence of a few foolish persons could make it worth a moment's consideration. But that persistence makes it necessary to speak out. Some quote the law in France and elsewhere. I have had the opportunity of seeing the state of the profession in most continental countries, and I assert that the English system is in all respects preferable. But I have not space to argue the matter at length to-day. The bare proposal should rouse the general practitioners from their dangerous apathy, for it reveals how little some care for his rights—to say nothing of his welfare. They have already given away much by establishing midwives as an inferior order of practitioners. They are about to do nearly the same with nurses, and unless the general practitioner wake up and assert their rights they will soon be deprived of more. One member of the association has given notice that he will propose the adjournment of the discussion to 1909. He might as well say 2009. But the direct negative would be best and should be voted by a great majority, leaving the proposers alone in their naked selfishness and dishonesty.

Patients with rheumatoid arthritis often suffer with various anomalous symptoms which may or may not seem specially connected with the disease. It is noticeable, therefore, that cases are often recorded in which such symptoms are spoken of as associated with the rheumatoid affection. A paper at the Ophthalmological Society was read on the 28th ult. by Mr. W. M. Beaumont of Bath, in which he stated his observations on eye symptoms in such patients, and called special attention to contraction of the field of vision—a symptom of rather common occurrence. But he also mentioned transient obscurations of vision, ephemeral palsies of the external ocular muscles, anæsthesia of the conjunctiva or the cornea as not infrequent. He compared compound charts of male and female patients—twenty-four of the former and fifty of the latter—and found them alike, thus excluding hysteria as a cause of contraction of the field. He constructed these charts by noting the number of degrees from the fixation point outward in the twenty-four men, adding together and dividing by twenty-four to get the mean. The other meridians were treated in the same way, and thus an average field obtained. The same process was adopted for the fifty women. He found among his rheumatoid cases no central scotomata, no evidence of optic atrophy, no more than a proportionate contraction of the color

field. He commented on the Raynaud-like symptoms which sometimes were present and referred to Dr. Samuel Lodge's observation of contraction of the field in Raynaud's disease. He suggested that the contracted field might be due to the syncopal condition of the terminal retinal vessels. Further he showed diagrams of the field of vision in rheumatoid arthritis to prove that expansion of the field took place under the inhalation of amyl nitrite, whereas in healthy people no such expansion occurs.

With regard to the recent researches on cancer, some of which I have noticed in previous letters, I may now remark that Professor Farmer has communicated a paper to the Therapeutical Society which Sir Wm. Dyer, president, pronounced most valuable, adding that it proved how useful the science of Botany might be made to the medical profession. In the paper Professor Farmer epitomized the results of his researches in collaboration with Messrs. Moore and Walker, which show that cancer cells differ in development from normal somatic cells and the cells of other tumors, and resemble in a remarkable manner that of the reproductive cells. In both plants and animals the nuclei of the somatic cells divide longitudinally into rods or chromosomes, while those of reproductive cells divide transversely into oval or ring-like chromosomes, forming only half the number of those of the somatic cell nuclei. Cancer cells divide like these and possess the power of destroying somatic cells in contact with them, as is the case in the embryo sac of plants. This type of division will be found in some cells of all malignant growths, but not in the benign. Sometimes the somatic cells of plants change by this mode of division into reproductive cells, the cause of which has not been ascertained. The anomalies observed in malignant growths may obscure, but do not affect the change; they may perhaps be due to nutritional and other disturbances which are known to affect the nuclei of normal cells.

Dr. Wild asked whether the heterotypical division is met with in rodent ulcer or thyroid tumors. Dr. Rolleston said cells had two functions, metabolic or anabolic, but when the former is in excess they increase tumultuously and destroy other tissues, as in malignant disease. He asked if the heterotypical division had been found in the preliminary stage of mammary cancer. Sir H. Beevor remarked that the leaves of Begonia when bruised produced new plants, and asked if their cells exhibited similar change, to which query Professor Farmer was able to reply negatively, but in regard to this and other questions further investigation is necessary.

The Asylums Board has decided to expend £50,000 in building a new training ship to accommodate 600 boys.

The revaccination bill cannot come on before April. Other bills of interest to the profession are equally unfortunate in the ballot. The Government will introduce a bill to amend the Public Health Acts.

The Central Midwives Board professes itself unable to add the training of the Rotunda to its recognized curriculum, as the rules have been approved by the Privy Council. The board knew that the Rotunda was the first school of midwivery in the United Kingdom, or if not it was unfit for its duties.

Our Government is sending medical attachés to the seat of war to observe and report on the medical aspects of the struggle on both sides.

The Prime Minister has passed through his influenza satisfactorily. With the sanction of Sir D. Powell and Dr. Venning he will leave London for a ten-days' holiday in the country.

The Countess Howe distributed the prizes at the annual meeting of the London Volunteer Companies of the Royal Army Medical Corps, and unveiled a tablet recording the names of eighty-six members who served in South Africa. It seemed specially appropriate for her ladyship to perform this duty, as more than half the men named on the tablet were in the Imperial Yeomanry Hospital and Bearer Company, the origination of which was due to the countess. At the conclusion of a little speech Lady Howe asked leave to present a silver cup for proficiency in hospital duties.

The Teeth as a Factor in Digestive Diseases and Disorders.—J. A. Storck thinks that during dentition disturbances of the stomach and bowels increase in frequency. Cases of indigestion due to the neglect of the temporary teeth are frequent. If deformities of the vault, palate, and teeth are corrected in early infancy, much discomfort may be avoided and the patient saved from becoming a chronic dyspeptic. Bacteria multiply in a dirty mouth and tend to cause a loss of appetite. Digestive disturbances often disappear after proper care of the teeth.—*New Orleans Medical and Surgical Journal.*

Progress of Medical Science.

Journal of the American Medical Association, Feb. 27, 1904.

Table Wines: Are Their Use to Be Encouraged?—H. O. Marcy refers to the fact that water in fluids submitted to low temperatures becomes ice crystals entirely free from admixtures which the fluids contain. Newly-made wines submitted to this process part with their bulk without loss of their alcoholic or other essential qualities. Fruit juices submitted to the same process are easily concentrated in the most remarkable degree. Most delicious beverages can be made of these. They are beneficial, retain the flavors of the fruit, and their use is to be encouraged, as they are likely to lead to a lessened use of tea, coffee, and especially alcoholic stimulants. In the place of table wines as now used by the comparative few, and now believed to be demonstrative of positive injury when habitually taken, there will be furnished to the many the fresh juices of the grape and other fruits, which, constantly used from youth to old age, will be found healthful and invigorating.

Report on Two of the Children Operated on by Lorenz.—Detailed notes of the cases are given by H. M. Sherman. In one case the left thigh was found flexed on the pelvis to about a right angle, and abducted till it lay in the frontal plane of the body. Neither outward nor inward rotation was apparent. The leg was flexed on the thigh, but could be extended. In other words, the limb was in the attitude in which it was put in the plaster dressing by Lorenz. There was some atrophy of the muscles of both the thigh and leg. The femoral artery could not be compressed between the finger and the femoral head, as is normally the case, but the head was recognized external to the artery, and more superficially placed than usual in a position beneath the anterior superior iliac spine. The greater trochanter was in a plane posterior to that in which the head lay. It was placed at the level of the acetabulum. Whether or not it lay in the same frontal plane as the acetabulum could not be determined The head was in a subcutaneous position in the outer part of Scarpa's triangle, while the trochanter was somewhere behind and internal to it. The condition was not one favorable to any stable support of the pelvis on the femur, and an operation was done by the author, who fully describes it. He does not see how the patient was at all benefited by the Lorenz operations. In the second case, palpation following the removal of the splint showed the head of the femur to be in the outer part of Scarpa's triangle and very near to the skin. There was a little active motion, and more passive motion. The child had walked in his splint, but could not do so after the splint's removal. The conditions, on examination, were so similar to those in Case 1 that the author presumed the same amount of mischief was done, that the capsule had been torn and the head thrust through the rent out into the surrounding muscles, that around it had developed an adventitious thin capsule, and that the untorn portion of the capsule reached up behind the head to the upper part of the neck near the trochanter, while the acetabulum was still closed by the capsule stretched across it, from rim to rim. The author then describes the conditions found four months later, the leg having meantime been in use, and he cannot see in this case that the Lorenz manipulations have been of any material benefit. Skiagrams taken immediately on the removal of the Lorenz plaster splints illustrate the author's contentions.

Medical News, February 27, 1904.

The Internal Treatment of Diseases of the Bladder.—Louis Stern calls attention to the merits of the drug helmitol. His experience with its use has extended over six months. He finds that it can be given in much larger doses than urotropin, without exciting irritation, and that it is more uniform in its action. The reaction of the urine seems to exert no influence upon its sterilizing effect, and this factor can be ignored during its administration. In most of his cases the writer has had no opportunity to make thorough examinations of the urine, so he has not been able to determine its degree of antiseptic power. In cases in which the urine was turbid and filled with mucus or pus, it rapidly cleared up and lost its offensive odor. The drug seems to have some pain-relieving quality, for even before the urine had become perfectly sterile the tenesmus was often greatly diminished.

Chloroform in Labor.—Edwin Ricketts believes in the value of chloroform in labor. He quotes Simpson's rules for its use at this time. The inhaler should never be allowed to rest on the patient's face. The anæsthetic should be often replenished on the inner surface in 5 to 10-drop applications. Before administering the drug, the patient's confidence should be gained. The drug should never be forced on a patient. The patient should be in-

structed how to breathe it in slowly, and shallowly at first. Previous administration of morphine or whiskey is seldom necessary. Tongue forceps are an abomination. Anointing the face is unnecessary. The face should not be covered with a napkin or handkerchief, but the cloth should be held in the hollow of the left hand of the anæsthetist. The facial expression, the color, pupils, and breathing of the patient can then be kept under observation. The writer believes that pulmonary tuberculosis, with any of the heart lesions, diabetes or albuminuria are not contraindications to the use of chloroform.

Thrush.—H. Illoway, in describing this disease, says that though most often a trifling affection, that is readily cured with the aid of some simple remedy, it may nevertheless at times become a very serious trouble—serious enough to take the life of the child. It is known that the disease may develop in an infant otherwise healthy and with an oral cavity in a normal state. The parasite is always introduced from without. Even in many grave cases of gastrointestinal disease seen by the writer, careful attention to hygienic requirements wherever faithfully given, prevented its development. The infant thus afflicted will not or cannot nurse. As a consequence inanition soon sets in and a rapid deterioration of vitality ensues. In earlier years the writer used the hyposulphite of soda in combination with glycerin and distilled water. This was given internally, and applied topically with a large camel's hair pencil. In severe cases he uses half a drachm of tincture of iodine in three and one-half drachms of glycerin. This mixture is applied with a large camel's hair pencil to the tongue, gum, and cheeks. The effect is remarkable, the parasite apparently melting away.

New York Medical Journal, February 27, 1904.

Frontal Sinusitis and Ophthalmoplegia Interna Partialis.—H. M. Fish gives the histories of five cases, and concludes that the most constant symptom in frontal sinus disease, and hence the one most complained of, is eye-strain or asthenopia due to a paresis of accommodation, and this holds true with both acute and latent sinus disease with exacerbations. In general, he concludes that ophthalmoplegia interna partialis coming on suddenly, appearing at different intervals and of variable degrees (position of near point changeable) in an emmetropic eye, or one made so by correction, when not attributable to some known cause, is very suggestive of a sinus involvement.

The Comparative Digestibility of Raw, Pasteurized, and Sterilized Milk.—T. M. Price has made a series of six experiments by feeding to calves milk in the three forms indicated in the title of the paper. In all but one of the series the digestive coefficients were in favor of the raw milk. Sterilized milk, which is generally supposed to constipate, produced the opposite effect in the calves. He admits that it is difficult to determine without further experiments how these results would compare with the results from these same varieties of milk when given to infants. There is a wide difference between the digestive organs of calves and infants, and the former are less sensitive than the latter, but any milk condition which proves harmful to the calf should certainly be looked upon with suspicion with reference to the human infant.

The Necessity of a Reliable Sign of Complete Anæsthesia.—C. S. White does not believe that we have any reliable sign of complete anæsthesia. The loss of the corneal reflex is unreliable. The condition of the pupils cannot be relied on. He states that in several instances coming under his personal observation, the anæsthetic was given slowly but the pupils did not contract, although the patient was undoubtedly under the influence of chloroform, and in another instance, in order to keep the patient relaxed, the iris was scarcely visible and did not react to light, while the pulse remained good and no especial evidence of shock was reported subsequently. Simply because the patellar reflex is lacking or the jaw clonus is present, we cannot say that a pathological condition exists. The rule holds good with the action of the pupil. Occasionally the pupils are irregular, and in another instance adhesions may be an obstacle to the free action of the muscle, and in highly nervous or sensitive individuals, the iris may be most capricious. All in all, this is a guide that is far from infallible and entirely too much confidence is placed in it. A sign which has appeared more constant, is the stretching of the sphincter ani; the patient if deeply anæsthetized remains perfectly quiet and breathes naturally during this period; but for obvious reasons this test is not applicable in all cases.

American Medicine, February 27, 1904.

The Treatment of Cervical Adenitis.—F. S. Bulkeley concludes his paper with the following summary: Many cases of cervical adenitis will be seen in which the avoidance or minimizing of scar is of great importance, and in which radical operative measures are not demanded. In such cases aspiration, or the use of a seton, or both, while not infallible, may prove successful. While such measures might be successful in cases of tuberculous glands, they are attended with possible dangers, and when tuberculous glands do not subside under medical treatment, excision, done with extreme care and reasonably early, is the method of choice. Neither aspiration nor the use of a seton should be resorted to in cases involving the deep cervical glands.

The Pathology of Leukæmia.—Edward T. Williams declares that as there are two distinct forms of leucocytes, originating respectively in the marrow and lymph-glands, pathology shows that there are also two distinct forms of leucæmia, according as the primary disease (leukosis) is seated in the marrow or glands. In medullary leukæmia, the commoner of the two forms, the primary disease is in the marrow. The red marrow loses its color and becomes whitish pus-like (pyoid). The microscope shows a marked hyperplasia of marrow cells of all types. The eosinophiles particularly are present in large numbers. Among these are numerous spermin crystals, the common products of decomposing nuclein. The red corpuscles are diminished in number with an unusual preponderance of erythroblasts, as in pernicious anæmia. Secondary deposits of the same character are commonly found in the spleen and lymph-glands, and often in the liver, kidneys, lungs, and other organs. The blood is always surcharged with the same elements. Lymphatic leukæmia is a rarer disease and differs essentially from that just described. The primary affection is in the lymph-glands. These glands are enlarged, whitish on section, and overloaded with lymphocytes. No form of marrow cells or eosinophiles is found in lymphatic leukæmia. Secondary deposits of a similar character are found in the spleen and marrow, and sometimes in other organs. The blood is surcharged with lymphocytes, great and small. These facts seem to prove the duality of the leucocytes.

Retroperitoneal Infection a Result of Appendicitis.—I. S. Stone after concluding that very many fatal cases of appendical disease are directly due to retroperitoneal infection, considers the question of the spread of infection to the deep-seated tissues and organs in question. It may proceed directly through the peritoneum to the cellular tissue behind from an intraperitoneal abscess (necrosis). It may reach the cellular tissue from a rupture (perforation) in a congenitally displaced appendix (retrocæcal), or rupture into the mesoappendix, and this may be accomplished without intraperitoneal infection. Infection may travel by way of blood or lymph channels. Communication between the appendicular and the portal veins by way of the ileocolic and splenic veins is direct, and accounts for many of those dangerous infections of the liver and other organs. The direction of the diseased appendix has much to do with the results of its infection and possible perforation. Persistent high temperature and quick pulse after appendicectomy should always suggest "posterior" complications. In the "delayed cases" such symptoms are very significant. When retrocæcal or retroperitoneal infection is suspected as a complication of appendicitis, a careful search for the infected area, as a rule, should be made, and drainage by the posterior route be provided whenever practicable. In certain septic cases, investigation of the retroperitoneal space should be made with the same care as that of the cavity of the peritoneum. Every "delayed case" should be considered with anxiety, lest there should be retroperitoneal infection. A guarded prognosis should be given in every case of appendicitis ushered in by, or complicated by, chills or any symptoms of sepsis. In operating on such cases, retroperitoneal infection should be considered as already started. The discovery and proper treatment of such infection is quite as important as the usual intraperitoneal technique. In view of the possibilities of retroperitoneal infection, a great responsibility is assumed by advising non-intervention in appendicitis.

The Lancet, February 20, 1904.

Cæcal Concretions.—A. Forsyth believes that the cul-de-sac of the cæcum often contains concretions. They are below the ileocæcal valve through which fresh fæces pass freely over them, and are not dislodged by the ordinary enemas. Under the name of "loaded cæcum" he recognizes a pretyphlitic stage of appendicitis. Some of these patients are melancholy women who become emaciated and despondent; some are young, healthy men, who rely on aperients to keep their bowels open, but go about their work with the same saddened anxious face and malnutrition. A third type is the "borborygmous" type, the patient who goes about all the time with the bowel full of gas. Persistent ene-

mata carefully given with large internal doses of olive oil will generally clear out the cæcum, and the exciting cause of many appendicitis attacks is thus removed.

A Case of Backward Dislocation of the Humerus Caused by Muscular Action.—The case is reported by Mansell Moullin and A. Keith, their patient being a stocky man of middle age, who received his injury while at tennis. Trying to take a ball breast high with a backhand stroke, he missed his aim and immediately his arm dropped by his side useless, and he felt a violent pain in his shoulder. When seen by the surgeon the patient was sitting in the characteristic attitude nursing his elbow, which was flexed and pointing slightly forward. The whole shoulder seen from the outer side had a peculiarly squared appearance. The arm was a little abducted and rotated inward; there was a great hollow under the deltoid in front, so that the anterior portion of the glenoid fossa could be felt through the muscle, and there was a corresponding prominence behind. Active movement was impossible, and any attempt at passive motion caused great pain. The patient was placed under an anæsthetic, and as soon as the muscles were relaxed the arm was slightly abducted, drawn downward, and rotated outward. The head of the bone slipped in at once and there was no further trouble, the patient regaining perfect use of the arm in the course of a few weeks.

The Use of Antistreptococcic Serum in the Treatment of Scarlatina and Diphtheria.—F. P. Mackie notes the discrepancies in the reported results in various diseases from the use of the serum, and they are due to the fact that bacteriology has not yet decided the relationship between the various forms of cocci met with in quite dissimilar maladies. His experience with serum in scarlatinal disease is summarized in the following statements: (1) Antistreptococcic serum is of distinct value in a certain number of cases of scarlet fever, particularly in those in which the throat lesion is severe and toxæmia is going on. (2) Bacteriological examination will give no sure guide as to the cases in which serum will be beneficial, therefore it is advisable to give the serum early and to make the bacteriological examination afterward. (3) The serum ought to be given early in the disease, just as in diphtheria. The longer the disease has lasted before the serum is used the less likelihood is there that it will be beneficial. Antistreptococcic serum is too often brought in with the strychnine and oxygen when it is unreasonable to expect it to do good. (4) If the first dose or two have no effect on the temperature its continuation will probably not be of any value. (5) The serum is liable to produce urticario-erythematous rashes. (6) Even in those cases in which it does no good there is no evidence to show that it does harm.

In regard to the use of antitoxin and antistreptococcic serum in diphtheria cases, Mackie's experience has been the common one that the severity of a given case varies directly according to the admixture of the streptococci with the Klebs bacillus. He is strongly of the opinion that when there is good evidence of sepsis—*i.e.* sloughing of the throat, marked cervical swelling, and a high fever, the serum should be given in addition to the antitoxin. He adds that in most cases of diphtheria in which death occurs during the first ten days, the patients die from the septic rather than the diphtheritic element. Moreover, most post-tracheotomy fatalities in diphtheria cases result from septic infection, and here the serum is certainly indicated.

Cancer in Australia.—In the previous issue, G. C. Adams discusses this question, concluding in the present number. The paper is in general a comparison with cancer in other countries and a consideration of a specific treatment for the prevention and arrest of the disease. He concludes (1) that cancer is not due to a bacterial or parasitic origin; (2) that cancer is a constitutional disease due to a specific or malignant virus originating in the blood and chiefly manifesting itself after thirty-five years of age and at its greatest virulence between fifty and seventy years of age; (3) that malignant disease may be congenital and certain forms acquired by infection or contagion; (4) that the principal factor in the cause is hereditary tendency; (5) that the principal exciting factor is prolonged local irritation acting on a constitution suffering from an inherited tendency or which has been debilitated through want of treatment of one or other of the following diseases in their order of frequency: syphilis, alcoholism, obesity, rheumatism, gout, and tuberculous disease; (6) that the principal dietetic factors in the causation are sugar, beer, and alcohol; (7) that the principal hygienic factors in the causation are woods and forests whose dropping foliage decomposing causes stagnation of water; also badly formed streets and defective drainage in cities, and the overcrowding of the badly housed and fed population of cities; (8) that cancer is a preventable disease, but the absolute cure is only to be found in the means for preventing its exciting causes and completely removing the same; (9) that the sanitary indigenous foliage of the following natural orders—(*a*) myrtaceæ, (*b*) lauraceæ, and (*c*) coniferæ—appears to exert a specific influence in rendering the native-born population of the countries where they grow almost immune from malignant diseases other than might be caused by prolonged irritation (the Australian eucalyptus, belonging to the myrtaceæ, exert the greatest influence in this direction); (10) that a eucalyptus oil obtained by means of a scientific preparation from various species grown in Australia possesses a specific action in arresting the pathological progress and process of malignant disease; and (11) that all internal and local treatment of a poisonous or irritating nature should be absolutely avoided, more particularly such local treatment as the *x*-rays and Finsen light, as they are likely to set up secondary conditions around the site of lesion. Far better is early and prompt removal when the malignant growth is accessible.

British Medical Journal, February 20, 1904.

A Case of Primary Quadruple Amputation: Recovery.—E. Harrison reports this case. The patient had been run over by a train so that the four extremities were crushed. A subcutaneous injection of strychnine was given, as well as an intravenous infusion of decinormal saline fluid. Four pints were infused in which was ℥x of adrenalin. Two surgeons performed the operations. The right leg was amputated about four inches below the knee; the left thigh about the junction of the upper and middle third, while both fore-arms were amputated about two inches above the wrists. The patient made a satisfactory recovery. The infusion with saline fluid and administration of adrenalin, together with rapidity in operating, were doubtless important factors contributing to a successful issue.

The Treatment of Appendical Abscess in the Recto-vesical Pouch.—Edmund Owen, in speaking of the various positions in which the appendix may be found, says that there is no organ in the body which is so regardless of anatomical proprieties as the appendix. There are two grave objections to opening an appendicular abscess through the vagina or rectum. The first is that the operator cannot tell exactly what he is doing. The second is that the operation may be followed by a fecal fistula which absolutely refuses to close. By adopting the abdominal route, the surgeon may be able not only to clear out the abscess, but to remove the diseased appendix. The writer believes that if an individual has had one unmistakable attack of appendicular inflammation, the appendix would better be resected as soon as the inflammation has quieted down. He has been much impressed with the danger of delay in operating, of the comparative slight amount of risk which the early operation involves, and of the great sense of relief and freedom from anxiety which it affords.

Congenital Narrowness of the Pyloric Orifice a Cause of Chronic Gastric Disease in the Adult.—A. Ernest Maylard considers that the normal caliber of the pyloric orifice during life and under relaxation is from 12 to 15 mm. In one of his cases the writer found, when operating, the orifice incapable of admitting the apex of the index-finger. This experience first led him to doubt that these narrowed orifices were spasmodic in character, but were rather due to some abnormality in development than to any acquired cause. The writer thinks this condition due to an excess of reduplication of the pyloric fold, whereby the valve width is increased but the orifice correspondingly diminished. It is, therefore, purely anatomical and congenital in its origin. The most suggestive symptoms of the condition are as follows: The existence of obstinate gastric symptoms during young adult life, not to be accounted for by any of the usually recognized causes, functional or organic. Often the patient is in a fairly good social position, and often one of a family otherwise healthy in all its branches. The patients are mostly women under the normal standard, both in stature and build. Great improvement always comes from dieting, while a renewal of the symptoms takes place with the return to a normal state of living. The writer believes that the proper treatment is gastrojejunostomy, performed with due regard to the normal disposition of the parts after operation.

Aseptic Surgery in Theory and Practice.—Charles Barrett Lockwood has for some years used a mixture of alcohol, water, and biniodide of mercury for disinfecting the skin. As to the use of gloves, the writer has found it practically impossible to complete an operation without tearing or puncturing the fingers of the gloves. He cannot perform certain operations, especially ab

dominal operations, to his own satisfaction if the sense of touch is hampered with gloves. For operations upon septic cases he believes that gloves ought to be worn, especially if other operations are impending. The degree of certainty with which the skin of the patient can be disinfected depends upon the region. The patient's skin is far more difficult to disinfect than the hands of the surgeon or of his assistants. The writer declares himself as exceedingly dissatisfied with the result of his efforts to disinfect skin. As to sutures, on the whole there is no better material than twisted silk for buried sutures and ligatures. In spite of the efforts of numerous investigators and inventors, catgut still remains an object of suspicion. The writer thinks this is to be deplored because it is an admirable substance for a variety of surgical purposes. He invariably uses catgut for septic wounds. It is invaluable for operations about the rectum and perineum. It is also best to use catgut when there is reason to suppose that the wound is tuberculous. But although some specimens may contain no infective organisms, they may contain ptomains which set up and localize suppuration. The writer has not had very gratifying results from the use of silver wire, but he approves of the use of a layer of silver foil for covering wounds. The wound by this means is kept dry, with the entire absence of any trace of redness or œdema. The writer finally treats of the question of sponges. He declares that he is by no means convinced that sponges prepared by the sulphurous acid method are infective. But, he adds, we greatly need a thorough investigation of disinfected sponges by the most rigorous and recent bacteriological methods.

Deutsche medizinische Wochenschrift, February 4, 1904.

Attempts at a Serum Diagnosis of Carcinoma.—Mertens describes attempts he made to elaborate a precipitin reaction for carcinoma, but like Engel, who recently published similar experiments, his results were unsuccessful. He injected rabbits with extracts from carcinomatous growths, and endeavored to obtain specific precipitations with the blood of carcinoma patients, The results were inconstant, not all the cancer patients reacting positively, while some healthy individuals did give a reaction. The author is not discouraged, however, and discusses the possibilities of the production of a curative serum.

The Value of Rubber Gloves in Manual Extraction of the Placenta.—Baisch enumerates the features which make this one of the most hazardous obstetrical operations, chief being the facts that it must often be performed hurriedly without time for proper hand sterilization, and that during the act of removal all germs present are necessarily actually inoculated into the huge open wound represented by the interior of the uterus. Under these conditions the use of rubber gloves is of the greatest advantage, and since their use the mortality in these cases has fallen to 0 per cent. in the Tübingen clinic, while in other large institutions it is in the neighborhood of 3 per cent. In Tübingen the number of patients running an absolutely normal course after manual extraction is 70 per cent. in Berlin and Munich; where gloves are not used it is 51 per cent, and 38 per cent. respectively. In addition to the actual advantage attending the use of gloves is the consolation, in case the patient does badly, that nothing was left undone to ensure her safety.

Phthisiogenesis and the Struggle against Tuberculosis.—E. v. Behring takes the ground that the tendency to acquire tuberculosis is formed in infancy, and that the so-called predisposition to the disease consists in an infantile invasion of the blood and lymphatics with tubercle bacilli. Pulmonary tuberculosis is to be regarded as the last stage of this early infection, which during childhood runs a latent course, but induces an increased susceptibility of the lymphatics and vessel walls to the tubercle toxin. The author's view of the tuberculous disposition is therefore different from that usually accepted, as he considers that it is not acquired through transmission by inheritance, but only through infection in infancy. In order to combat the infections in the cradle which may become pulmonary lesions later in life, the author says that until the time arrives when we begin to employ for infants the same protective inoculations he has successfully used in calves, we must prevent the tubercle bacillus from gaining access to the mouths of babies, and must administer tubercle antibodies with their milk. Owing to its mode of formation, freshly secreted milk contains antibodies in abundance, but many factors, such as heat, cold, long standing, the development of bacteria, etc., quickly destroy them. The author proposes to ensure their preservation by adding formalin in the strength of 1–10,000, to the fresh milk. This does not impair its nutritive value, and the results in the raising of calves have most effectively demonstrated the value of the plan.

Berliner klinische Wochenschrift, February 8, 1904.

A Contribution to the Therapeutics of Neuralgias and Myalgias.—Meyer says that the ordinary coal-tar analgesics, as well as the various systems of hydrotherapy, massage, etc., often fail to subdue obstinate neuralgic conditions. In such cases he has found that hydrochinon does excellent service. He employs it in doses of one to four grams daily, and usually gives it in solution at bed-time. The solution should be fresh, and not be exposed to the light. No unpleasant effects were noted, except in one case in which nausea, tachycardia, and vertigo were produced, but quickly subsided on stopping the drug.

A Case of Congenital Bronchiectasis with Transposition of the Viscera.—Siewert describes the case of a young man of twenty-one who since childhood had had attacks of coughing, accompanied by the sudden expectoration of large amounts of purulent fluid. He was poorly developed mentally and physically, and a physical examination showed complete transposition of the viscera. There were also signs of a cavity in the left upper lobe anteriorly. In the absence of all evidence of tuberculosis, gangrene of the lung, etc., the author diagnoses the condition as a congenital bronchiectasis. This is a very rare condition, as only four cases were found reported in the literature.

Münchener medizinische Wochenschrift, February 9, 1904.

A New Symptom in Œsophageal Carcinoma.—Steiner describes a case in which the œsophageal bougie was observed to be drawn downward during inspiration and to move upward during expiration. The phenomenon was ascribed to adhesion of a carcinomatous mass to the diaphragm and the autopsy confirmed this view.

Permanent Tubage in Œsophageal Stricture.—Schiele treated an œsophageal stricture due to carcinoma at its lower extremity and which threatened to become impermeable, by carrying through it a short drainage tube on a bougie. The tube was perforated in the customary way, and to keep it from slipping into the stomach its upper end was perforated by a thread the ends of which were tied to a suitable tooth. The patient was in this way enabled to swallow fluids and semi-solids while the dilated lower segment of the œsophagus was kept drained. The tube was changed every five days and occasioned no discomfort.

Diagnosis with the Œsophagoscope.—Stark calls attention to the value of this instrument, which owes its development largely to the efforts of v. Mikulicz. The author places the patient in the recumbent position on one side and thoroughly cocainizes the pharynx, larynx, and upper part of the œsophagus. It is a mistake to hyperextend the head, as this flattens the œsophagus against the vertebral column and renders the introduction of the instrument more difficult. The technique of the examination is not difficult and the author was successful with every one of his last one hundred cases. Of forty-six patients recently examined, seventeen were carcinomatous, three had cicatricial lesions, two had foreign bodies, two had diverticula (traction), two had diverticula (Zenker's), three had diffuse dilatation, six had neuroses, one inflammation, and in ten complicated conditions existed which did not permit of diagnosis.

Artificial Ischæmia.—Müller has performed over seventy major operations on dogs, using suprarenin solution as a hæmostatic and reaches most satisfactory conclusions. The object of the experiments was to determine the value of this agent in controlling the hemorrhage from parenchymatous organs, particularly the liver and kidney during incision and resection. In order to produce satisfactory anæmia in such organs solutions of 1-1000 or 1-2000 are required, but in the skin, fatty tissues, and muscles a strength of 1-5000 or 1-10000 is most suitable. The agent does not appear to be poisonous in quantities ever likely to be used. The vasoconstriction is produced within two minutes and lasts for several hours. Resections of the liver may be performed entirely without parenchymatous bleeding by injecting the solution along the line of proposed incision; and deep dissections of the neck, chest, etc., may be bloodlessly performed in the same way. Slightly pink solutions are safe to use, but a deeper discoloration indicates dangerous decomposition. Capillaries and small vessels are completely occluded, larger vessels are constricted. There is no danger of secondary hemorrhage. When diluted with decinormal salt solution the injection of suprarenin is painless. The author has not yet repeated his observations on man, but is convinced that the agent will be found just as useful in major operations as it has already shown itself in minor surgery.

Book Reviews.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; one-time Clinical Professor of Diseases of Children in the University of Pennsylvania; Member of the Association of American Physicians, etc. Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Medical Dispensary of the Jefferson Medical College Hospital; Member of the Staff of the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis. Volume IV, December, 1903. Philadelphia and New York: Lea Brothers & Co., 1903.

THIS volume contains, among other interesting matter, a chapter by J. E. Hemmeter, on diseases of the digestive tract; one by J. C. Bloodgood, on various surgical conditions, including an excellent review of the literature of tumors, benign and malignant, with some interesting illustrations; William T. Belfield contributes a chapter on genitourinary diseases, and J. R. Bradford one on diseases of the kidney. The practical therapeutics are brought well up to date by H. M. Landis. As a whole, the volume compares very well with those that have already appeared in this series, the editor and publisher both evidently having a fixed determination to make the work all that they have promised for it.

FOURTH ANNUAL REPORT OF THE WORK OF THE CANCER LABORATORY of the New York State Board of Health, conducted at the Gratwick Research Laboratory, University of Buffalo, for the year 1902-3. Albany: State Department Printers, 1903.

JUST at this time, when the subject of cancer is exciting so much interest the world over, the report from the laboratory established exclusively for the study of this scourge, must challenge our attention. The report before us deals with an investigation of cancer districts; the etiology of cancer, its biology and chemical study; toxic and vital theories regarding its causation; statistics; the physics and therapeutic value of the cathode and ultra-violet rays; closing with an epitome of the history of carcinoma by Roswell Park, M.D. The work, taken as the result of careful investigation in a most important field, will be of decided interest to all those whose labors lie in the same direction.

ÜBER DIE PROGNOSE DER SYPHILIS. Vier Vorlesungen gehalten in den ärztlichen Fortbildungskursen zu Aachen, 1902-1903. Von Dr. G. MAYER, Geh. Sanitätsrat. Berlin: S. Karger, 1904.

THIS is a brochure of eighty-seven pages only, dealing, however, with the most important subject. It is arranged in the form of four lectures. The first, on the prognosis in syphilis in general specific brain and spinal-cord affections and general paralysis. The second, taking in tabes, syphilitic nerve affections, and syphilis of the heart and blood-vessels. The third is upon syphilis of the lung and liver. The fourth, includes syphilis of the kidney, diabetes and gout in their relation to syphilis. The chapters are all written in a pleasing style, and the subject matter is surely worthy of the careful consideration it has received.

A TREATISE ON ORTHOPÆDIC SURGERY. By ROYAL WHITMAN, M.D. Second Edition; revised and enlarged. Philadelphia and New York: Lea Bros. & Co., 1903.

THE second edition of this excellent treatise should meet with as cordial a reception as the first. Most of the chapters have been revised and extended; new illustrations and *x*-ray pictures have been added. Congenital hip dislocations, coxa vara, and tendon grafting, which have in recent years actively engaged the attention of the orthopedic world, are extensively discussed by the author.

THE PURIN BODIES OF FOODSTUFFS, and the Rôle of Uric, Acid in Health and Disease. By I. WALKER HALL, M.D., Assistant Lecturer and Demonstrator in Pathology, the Owens College, formerly Senior Demonstrator in Physiology at the Owens College, Victoria University of Manchester; Hon. Pathologist to the Salford Royal Hospital. Second Edition (Revised). London and Manchester: Sherratt & Hughes, 1903.

THE second edition of this small book deserves greater commendation than the first, if that were possible. A new chapter appears upon the action of drugs on purin excretion. Also some new tables and methods of estimation and preparation are appended. A noteworthy portion of the book is devoted to bibliography. This is exceedingly extensive and forms a veritable library of reference. The construction of the text is condensed and every word is made to count. As a book of reference and instruction upon the subject treated it is by far the most valuable that has yet appeared.

MAMMALIAN ANATOMY, WITH SPECIAL REFERENCE TO THE CAT. By ALVIN DAVISON, Ph.D., Ex-fellow of Princeton University; Professor of Biology in Lafayette College. Philadelphia: P. Blakiston's Son & Co., 1903.

THIS work is intended for the use of the undergraduate student in biology. The major portion is devoted to the gross anatomy of the cat, the various structures being taken up in their logical sequence. The introduction contains a small section on the minute anatomy of the tissues and the preparation and preservation of material for such purposes. There are 108 illustrations, all of which are well executed. The practical questions and suggestions which are appended to each chapter will be of great service to those compelled to take up the study of this subject without the aid of an instructor. As a work on comparative anatomy it cannot fail to find its place.

PATHOLOGIE UND THERAPIE DER RACHITIS. Von Dr. WILHELM STOELZNER. Berlin: S. Karger, 1904.

THIS monograph is written with characteristic Teutonic thoroughness, and rachitis is considered from every possible point of view in the most exhaustive manner. Much has been gathered from the European literature that is not generally known in this country, and the chapter on etiology is particularly interesting. The author considers all existing theories untenable, and tentatively submits that the disease may be due to the functional insufficiency of some organ analogous to the thyroid. This view is founded upon the general similarity between rachitis and cretinism, and the author suggests that the adrenals may possibly be the organs at fault. Therapeutically he has found a solution of phosphorus in cod-liver oil the most valuable agent.

DIE ERSTEN ZEICHEN DER NERVOSITÄT DES KINDESALTERS. Von Prof. H. OPPENHEIM. Berlin: S. Karger, 1904.

IN this address the author of what is perhaps the best known German textbook of nervous diseases rehearses the various abnormalities of psychical development in children which are often the first aberrations of a mentality tending toward later disaster. While such peculiarities may be, and often are, outgrown, still their timely recognition may be the means of preventing serious difficulties in after years and they deserve the attention of all interested in the problems of childhood.

LES TROUBLES GASTRIQUES DANS LA TUBERCULOSE PULMONAIRE CHRONIQUE. Par Le Docteur E. DU PASQUIER. Paris: G. Steinheil, 1903.

THE author discusses the clinical and prognostic features of the gastric disorders usually accompanying pulmonary tuberculosis, basing his conclusions on a series of eighty-four cases in which analysis of the stomach contents was made. He points out the paramount importance to the tuberculous patient of a good digestive apparatus and emphasizes the necessity of the examination of test-meals in order to carry on the treatment successfully. Every other consideration should be subordinated to the assimilative function and no drugs continued if they react unfavorably on the stomach.

CLINICAL TREATISES ON THE PATHOLOGY AND THERAPY OF DISORDERS OF METABOLISM AND NUTRITION. By Prof. Dr. CARL VON NOORDEN, Physician in Chief to the City Hospital, Frankfort a. M. Translated under the Direction of BOARDMAN REED, M.D., Professor of Diseases of the Gastro-intestinal Tract, Hygiene and Climatology, Department of Medicine, Temple College; Physician to the Samaritan Hospital, Philadelphia, etc. Part IV. The Acid Autointoxications, by Prof. Dr. Carl von Noorden and Dr. Mohr. New York: E. B. Treat & Co., 1903.

THIS little compend is a valuable addition to this series. The author presents the results of his investigations into the derangements of metabolism which are concerned with the formation of an excess of acid in the body. This subject is one of great interest to the clinician, for it is true, as said in the preface, that those physicians who successfully treat chronic diseases must carefully observe the digestion, excretion, and assimilation of their patients.

TUBERKULOSE-ARBEITEN AUS DEM KAISERLICHEN GESUNDHEITSAMTE. 1 Heft. Mit 5 Tafeln. Berlin: Julius Springer, 1904.

THIS contribution is divided into two parts, of which the first, by Kossel, Weber, and Heuss, is a comparative study of tubercle bacilli obtained from different species of animals. The results seem to show that in the majority of cases human tubercle bacilli differ in morphology and in cultural and pathogenic characteristics from those found in tuberculous cattle. Occasionally, however, bacilli are found in man which cannot be differentiated from those causing *Perlsucht* in cattle.

The second part, which is by Weber and Bofinger, discusses fowl tuberculosis and tends to show that the tubercle bacilli of fowls and of mammals possess clearly marked points of difference. The bibliography of both sections is especially valuable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 18, 1904.

Dr. ANDREW H. SMITH IN THE CHAIR.

The Hospital Car: Its Equipment, Uses, and Importance.—Dr. WM. W. SANFORD read this paper, and said that when the plan of having such a car was suggested to the Erie Railroad officials, a combination baggage car and smoker was selected for the purpose. By removing the double row of seats sufficient room was secured for six ordinary hospital beds supplied with mattress and rubber sheets. In the baggage compartment were operating table, sterilizers, oxygen, drugs, etc. Such a car would prove to be almost invaluable. The doctor showed drawings of a typical hospital car, and this he believed should serve as a type of several cars which should be distributed at certain distances along the roads. He then gave the details of the interior arrangement of such cars, which would be of great value to the companies, as well as to the injured, because of (1) saving of valuable time; (2) bringing to their aid a sufficient number of physicians and nurses; (3) equipment being always at hand. He believed that at present the large number of deaths from railway injuries was due to lack of immediate surgical and medical treatment, the lack of facilities for treating these patients, and the lack of time. The need of such cars seemed to him imperative.

Dr. ANDREW H. SMITH referred to the diminished liabilities of the companies from the results of accidents, and stated that things were different to-day from what they were a few years ago, when the life of a man was considered to be equivalent to $5,000. Then the companies were in pocket if the people were killed outright; if then they were injured and not killed there was scarcely any limit to the amount of damages claimed. To-day life was estimated by the earning capacity of the individual. In case an accident takes place and the company had made no provision for the care of the injured he said the sympathy of the juries would be against the company; but if such cars as suggested were provided sympathy would change in favor of the company.

The Rationale of the Natural Arrest of Consumption; a Study Explaining the Effects of Sea Voyages, with Suggestions as to the Ideal Treatment.—Dr. W. B. MCLAUGHLIN of Austin, Tex., read this paper. (See page 367).

Dr. GEORGE L. PEABODY said he failed to see how a practical turn could be applied to Dr. McLaughlin's remarks or how any practical deductions could be drawn from this artificial environment. A near approach to such a sterilized atmosphere could be had when people lived in the deserts of Egypt. Years ago a colony of consumptives had lived in a hotel near the pyramids, and they, he thought, breathed sterilized air. The same thing could be accomplished in mid-ocean. But how such could be brought about artificially seemed to him a very difficult problem. He spoke of a semi-charitable, organization society that, a few years ago, was engaged in establishing a home for the treatment of consumptives, and one of the Board of Managers asked him to make some suggestions, that they did not want to feel restrained by ordinary limitations, but they wanted certain compartments where patients could breathe air from the heart of the Adirondacks and other compartments where they could breathe the air of mid-ocean, etc. Of course such a thing was practically impossible. To him it seemed difficult to give a practical hearing to Dr. McLaughlin's extremely good theoretical remarks.

Dr. JOHN B. HUBER said that tuberculosis when due to the tubercle bacilli was not particularly fatal, and only when the mixed infection occurred was the disease rendered serious. Therefore, it was of great importance to attempt to do away with the possibility of mixed infection. Sterilized air was important, too, but there were other things to be considered, such as dry air for some, moist air for others, sea air for some, and land air for others, etc. Tuberculosis was the resultant of many factors; the tubercle bacilli were originally saprophytes, and fed upon dead or decomposing material. An interesting subject referred to the devitalizing tissues of the body, and, he said, tuberculosis depended upon the condition of the bacillus and other microorganisms as well as upon certain predispositions, vicious heredity, alcoholism, poverty, and the like, in the body which made it susceptible to the onset of various bacteria.

Col. W. C. GORGAS said that the main idea of the paper was new to him, but he believed it to be very important as bearing upon municipal sanatoria. He emphasized the importance of a liberal supply of air. Patients taken to such a municipal hospital or sanatorium and treated in the way proposed he believed would get well in three or four months instead of eight or ten months, and so would be a great saving to the city.

Dr. S. A. KNOPF advocated better teaching of the masses, that rooms should be better ventilated, that the dark, foul, and filthy rooms should be abolished, and, therefore, much could be done in a prophylactic way. The value of sea air was shown in those children especially who were sent to the sea-side with tuberculous bone and joint disease. In many coughs disappeared. A sojourn at the seaside seemed invigorating and so did good. In dealing with the tuberculosis problem, he said we should seek continually after the ideal, but we should also do away with what was impractical. To obtain an aseptic atmosphere was impractical, but it was practical to teach the masses the love of pure air. He said that if the municipalities did their duty they would see that the street cars were better ventilated, and make other changes which would result in making traveling facilities better and less dangerous.

Dr. MCLAUGHLIN believed that if what he proposed could be carried out it would be a great advance in the therapeutics of tuberculosis. So far as sterilizing the air was concerned, he said that a great step toward this end would be in removing the dust.

Dr. S. A. KNOPF referred to the death of Peter Dettweiler at Cronberg, Germany. He gave much to the cause of phthisiotherapy, his greatest achievements being the incorporating of the rest cure on a reclining chair in the open air and the foundation of the first sanatorium for the consumptive poor. He said that Germany was much indebted to him for its numerous sanatoria.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 19, 1904.

LEWIS A. CONNER, M.D., CHAIRMAN.

Chronic Valvular Disease of the Heart; Pulsating Liver.—Dr. S. S. BURT presented a case of chronic valvular heart disease in connection with the paper which he presented later. The patient was a man, thirty-four years of age, who came first under observation in 1899. He had been an intemperate drinker of beer for twelve years, having taken at times as much as one hundred glasses in twenty-four hours. Shortness of breath on walking began about five years before. At that time he complained of dyspnœa, enlargement of the legs and abdomen, and of prostration. Examination showed œdema of the lower extremities, cyanosis of the lips, marked pulsation of the vessels of the neck, ascites, hypertrophy of both sides of the heart and excessive dilatation. The liver extended from the fourth rib down to the level of the umbilicus on the right side. There was a heaving, expansile pulsation of the liver, due to regurgitation into the hepatic veins themselves. He was treated by paracentesis abdominis and saline laxatives, with strychnine and rest in bed. In a few weeks he was improved in almost every way, and finally the tricuspid thrill disappeared, though the mitral systolic and presystolic murmurs were still present. At

the present time, there was a distinct systolic murmur over the mitral area; there was regurgitation of the blood in the superficial and deep veins of the neck; there was moderate pulsation of the liver; the legs were only very slightly œdematous. Aside from the congested state of the liver, due to the heart disease, it was probable that the man also had hypertrophic cirrhosis of the liver.. The speaker said that he had seen very few cases of pulsating liver secondary to a cardiac condition in a very large experience with heart disease. He had occasionally met with tricuspid regurgitation secondary to mitral disease, but none so extensive as this one.

Ascites; Hepatic Cirrhosis; Tuberculous Peritonitis.—Dr. WILLIAM B. NOYES exhibited a small section of the liver taken from an Italian, forty years of age. who had been in the service of Dr. F. C. Keller at the Columbus Hospital. The man had been in the habit of drinking three or four glasses of whiskey a day, and before breakfast. Shortly before admission to the hospital, the abdomen began to swell and become painful. On examination, the liver and spleen and genitals were œdematous. There was no jaundice. Over four quarts of clear and highly albuminous serum were drawn off from the abdomen. The urine was free from albumin. On December 6, six quarts and a half were again drawn off. The liver dulness was increased one hand's breadth below the margin of the ribs. The patient died on December 10. At the autopsy, the peritoneal cavity contained 4,000 c.c. of clear yellowish serum. The peritoneum was studded with minute white tubercles. The omentum was agglutinated to the intestines. The liver was bound down on all sides to the adjacent viscera. It weighed 67 ounces. There was marked perihepatitis. The bile ducts were dilated and filled with masses resembling inspissated bile. There were no tubercles in the liver. There were no stones in the gall-bladder, and the common duct was patent. The intestine was covered with minute tubercles. The duodenum and jejunum were closely adherent to adjacent viscera. The right lung was collapsed and consolidated from the pressure of a large pleural effusion. The supposed increase in liver dulness was due to a solid mass of omentum, the result of tuberculous peritonitis. How much of the ascites was due to the tuberculous peritonitis, and how much to the condition of the liver, it was impossible to say. The liver was the seat of a hypertrophic cirrhosis. The speaker said that clinicians very commonly classified cirrhosis of the liver under two heads, hypertrophic and atrophic, but, according to the pathological classification of Adami the subject was much more complex. Adami divided cirrhosis into seven varieties, viz.: (1) Portal; (2) biliary; (3) pure cellular cirrhosis; (4) arterial cirrhosis; (5) central lobular cirrhosis; (6) secondary cirrhosis, and (7) sporadic cirrhosis. The liver under consideration appeared to belong to the variety of obstructive biliary cirrhosis, this diagnosis being made chiefly from the obstruction of the bile ducts. The microscopical examination showed a very fatty liver and a very small amount of connective tissue in a very early stage of formation. If the man had not had the tuberculous peritonitis, which caused his death, he would have probably lived a long time despite the hepatic cirrhosis.

Dr. S. A. KNOPF thought there was no other way of distinguishing ascites due to cirrhosis of the liver and ascites dependent upon tuberculous peritonitis than by withdrawing some of the fluid and injecting it into guinea-pigs.

Dr. BURT referred to a case of cancer in which the performance of paracentesis abdominis resulted in a fragment of cancerous tissue coming away in the fluid. This led to the diagnosis of colloid cancer, a fact which was very suggestive of what might perhaps be accomplished by this mode of investigation. Fluid removed in this way should be subjected to microscopical examination as a routine measure.

Dr. S. A. BROWN referred to a case of peritonitis with loculated fluid. About sixteen ounces of fluid were withdrawn for diagnosis. On examining this after sedimentation, small colloid masses were visible and were very characteristic. The diagnosis of colloid cancer was confirmed by the autopsy.

Dr. L. A. CONNER said that the demonstration of tubercle bacilli in the serous fluid removed by aspiration was often very difficult, and the necessary delay of six weeks or more after the inoculation of a guinea-pig was a serious objection to that mode of investigation. But between an inflammatory exudate, such as occurred in tuberculous peritonitis and a stasis exudate, such as occurred in portal obstruction or cardiac disease, there were distinct differences, such as in the specific gravity and the presence of traces of nucleoproteid. The hydræmic transudates gave a very low specific gravity, usually 1008 or less; the stasis transudates of cirrhosis or cardiac disease gave a specific gravity of 1009 to 1012, and the inflammatory exudates usually showed a specific gravity of 1018 to 1025. In tuberculous peritonitis the specific gravity was usually 1015 to 1025. If the albumin were estimated by Esbach's method, or better still, by weighing, some differences would be observed. In the hydræmic transudates there would be hardly more than a trace of albumin, in the stasis transudates the amount of albumin was usually 1 gm. to the litre, or 0.1 per cent., although it was sometimes as much as 1 per cent.; in the inflammatory exudates the quantity of albumin was very large, sometimes as high as 2 or 3 per cent., or 20 to 30 gm. to the litre. The nucleoproteid was much more apt to show in the inflammatory than in the other exudates.

Dr. Burt said that it had been recently demonstrated that nucleoalbumin could be shown very nicely by intravenous inoculation of the material into animals. Within a few minutes the whole venous system became clotted, and the animal died. If the heart were rapidly opened, a long string of blood-clot could be drawn out.

Multiple Serositis and Extreme Myomalacia.—Dr. LEWIS A. CONNER presented pathological specimens taken from a Chinaman who entered the Hudson Street Hospital a few weeks ago in a moribund condition. A diagnosis of pneumonia was all that there was time to make. The autopsy revealed, in addition to the pneumonia, a condition of multiple serositis, a complete synechia of the pericardium, adhesions of the pleural cavities at their bases, extensive perihepatitis and perisplenitis, and more or less chronic peritonitis. The heart was of special interest. The two layers of the pericardium were everywhere adherent, and there was a dense fibrous mass binding down the heart. The organ itself was considerably dilated. There were a few antemortem clots in the dilated ventricle. The most noticeable feature was a large area of diffuse yellow material in the wall of the left ventricle. It was firm in consistence, and the microscope showed an extreme condition of fatty degeneration of the heart muscle, in some places going on to the point of liquefaction. The coronary vessels were examined with great care, but were found to be practically normal, though the small branch of the coronary artery running to this softened area was very small. However, on examition of the intima and sections very little pathological change was discovered. It was, therefore, very difficult to explain satisfactorily the great diminution of this vessel and the softening of the heart muscle. The great mass of fibrous pericardium lay directly over the thin-walled arteries, and this suggested the possibility that this dense fibrous casing for the heart might, in some way, have caused sufficient constriction to give rise to this very extensive softening.

Dr. C. E. QUIMBY suggested that it would be well for physicians to bear in mind that there were many defects in creation, and that there was no more reason to expect perfection in all of the organs and tissues of the body than to expect every person to have the same size and shape of nose.

Miscellaneous Points on the Palpation of the Chest.—Dr. WILLIAM N. BERKELEY read a paper with this title. He said that, as a rule, the books on physical diagnosis were rather lacking in information on palpation for diagnosis. The average physician seemed to think that, in comparison with auscultation, all other methods of physical diagnosis were insignificant.

Vocal Fremitus.—The speaker said that fremitus might be classified as: (1) Rhoncal; (2) tussive; (3) borborygmic; (4) pleuritic; (5) succussive; (6) cardiac and vascular, and (7) vocal. His remarks at this time were limited to the consideration of vocal fremitus. When egophony was absent, it might be made apparent to the ear by the phonation of the short "oo" as in foot. Vocal fremitus was more reliable when the patient could retain the pitch throughout the test. The vibrations of the voice had a quality as well as a pitch and an intensity. The variation of the fremitus with the varying loudness or intensity of the voice was familiar to all beginners. The lower the pitch, the fewer the vibrations present, and the fewer these vibrations, the more perceptible the individual waves became to the palpating fingers. With women and reasonably intelligent children over six years of age, marked improvement in the fremitus could be obtained if the patient were told to speak in as deep a voice as possible instead of in the usual shrill tone. Palpation of the fremitus should be done with the palmar surface of the forefingers of the hand the observer is most accustomed to use. He did not think the side of the palm was a good surface for the performance of palpation. Two symmetrical areas of the chest should, of course, be compared, but this comparison should be made, not with the two hands, but with the same hand. A highly trained tactile sense was often capable of extraordinarily fine discrimination. It was usually stated that fremitus was conveyed to the chest through the windpipe. This doubtless was true, but it seemed reasonably sure that the elastic walls of the trachea and bronchi also assisted to an appreciable degree. Fremitus was likewise conveyed by the vertebral column and the ribs. Accumulations of fat and muscle on the exterior of the chest were not so destructive of fremitus as was usually supposed. Fremitus was usually universally larger on the right side than on any corresponding portion on the left side. He believed in 60 to 75 per cent. of patients, with the patient in the usual position for examining the back, right vocal fremitus below the angle of the scapula was absolutely larger than over any part of either the right or left chest. The excess on the right side was supposed to be due to the relative anatomy of the right and left bronchus. The excess of right fremitus was physiologically greater in persons between ten and twenty-five years of age than at any other age, a fact to which his attention had been called by Dr. A. A. Smith. This was probably of developmental origin. A numerical comparison of the normal right and left fremitus might seem far-fetched, yet he ventured to affirm that if the right subclavicular fremitus were denominated 3, that of the corresponding portion on the left side would be 2. He had found that a diagnosis of consolidation at the right apex, when the larynx fremitus was to the right fremitus as 4 to 2, or 6 to 3, was usually confirmed by the other signs. The causes of left-sided fremitus excess were: (1) Consolidation of the left side; (2) influences on the right side which dissociated the visceral from the costal pleura; (3) obstruction of the right bronchus, and (4) transposition of the viscera. Plaques of mucus, stenosis, foreign bodies, diphtheritic membrane, and the pressure of aneurysms, glands, and mediastinal tumors were among the obstructions of the bronchus to be thought of. In old women and small, anæmic children the relation might be changed by holding the chin high and rotating the chin to the left, thus artificially compressing the right bronchus. Supposing the loudness and pitch of the voice to be constant, the whole problem in vocal fremitus was to determine whether it was increased, diminished, or absent.

Dr. BURT said he would like to know why, on listening over a pleuritic effusion, vocal fremitus would be absent on palpation but would be present on auscultation. Vocal fremitus he esteemed very highly, and for that reason he greatly appreciated the paper presented by Dr. Berkeley.

Dr. JOHN HUBER thought the paper was very interesting in connection with the diagnosis of early phthisis, for tuberculosis of the bronchial glands was now generally considered to antedate the affection of the lung parenchyma. Possibly this involvement of the bronchial glands could be detected by vocal fremitus.

Dr. C. E. QUIMBY said that the ear was vastly more sensitive than the fingers, and that this seemed to him to explain the fact that vibrations could be detected by the ear when they were imperceptible to the finger. He would deny that, over fluid, one could sometimes obtain vocal fremitus and at other times could not. He believed that fluid in the chest, which would cut off vocal fremitus in one case, would do it absolutely in all cases in which fluid was present under similar conditions. Years ago he had arranged an apparatus in connection with the Helmholtz resonator by which one could optically demonstrate a valvular murmur by means of a glass flame. He would suggest that the same thing could be done more conveniently by the use of a powder It was also desirable to make use of a resonator that can be tuned to the pitch of the murmur or special vibration.

Dr. S. A. KNOPF said that there was evidently much yet to be learned concerning the science of physical diagnosis. He had been deeply impressed with the remarks made by the reader of the paper as to the sounds which the patient should be made to express. It was his custom to ask his patients to make a humming sound, and then ask them if they felt the vibration of their voice in any special direction. It was interesting to note that when there was beginning consolidation on one side or the other, the patient would often point to this spot as being the place at which the vibration of the voice was conscious to himself. Dr. Knopf said he had used this method as a means of diagnosis for a long time. When asking the patient to make a humming sound he also placed his hands over the chest, and thus readily appreciated the vibration.

Valvular Disease of the Heart and Its Treatment.—Dr. STEPHEN S. BURT read this paper. He said that without doubt many persons whose valvular defects had been proper compensated for were seriously injured by treatment. Treatment was not indicated unless the compensatory hypertrophy was followed by secondary dilatation. If there were progressive sclerosis, the duration of the compensation was always uncertain. Mitral stenosis and mitral insufficiency were about equal in their eventualities. Valvular disease in the first half of life, if properly compensated for, was not unusually especially dangerous in connection with pneumonia or with the use of anæsthetics, but the opposite was true in later life. The physician should endeavor in every case of organic disease of the heart to explain to the patient, without exciting his apprehensions, just the significance of the particular affection of the heart from which he was suffering. Plenty of sleep and fresh air, and habitual light eating were important factors in keeping up good health in such persons. Alcoholics should generally be avoided. Very hot baths, including the Russian and Turkish baths, were exceedingly dangerous, as was also swimming. Bathing was largely a matter of personal peculiarity. To condemn a person with heart disease to a life of inactivity was the height of bad management; such persons should have moderate exercise in the fresh air, but no violent muscular exercise should be allowed. The important thing was to insist upon moderation in everything—mental and physical exercise, eating and drinking. When rupture of

compensation occurred there would be dilatation of the heart, shortness of breath, possibly cyanosis, and cardiac palpitation. With regard to irregular pulse in mitral lesions, he would say that there need be no particular alarm on this point. Irregularity of pulse in aortic disease was commonly a serious manifestation. When hypertrophy of the heart had been overcome by dilatation there was but one course to pursue, and that was to make the patient understand the exact nature of his condition. When there was disturbed equilibrium, rest was of paramount importance; indeed, it was often all that was required. Massage, in properly selected cases, was often serviceable. The various baths, such as the Nauheim baths, were more suitable for functional than organic lesions. Where venous engorgement was excessive, and there was much distress therefrom, great relief could be obtained from venesection. Many of the cardiac symptoms were effectively relieved by small doses of calomel. After a large experience, he looked upon digitalis as one of the few drugs that were indispensable. It could only work mischief, however, when there was a perfect adjustment. This drug slowed the heart and strengthened its contraction. The proof of the value of the remedy rested upon the good results that followed its employment, and worth more than a vast amount of ingenious theorizing. When there was much anasarca it was sometimes necessary to overcome the tention by puncture of the limbs before the digitalis would act properly. Ordinarily, the tincture of digitalis should be given in doses of from ten to twenty minims, and the infusion in doses of one to four drachms at intervals of three or four hours. When, for any reason, it was desirable to substitute some other drug for the digitalis, the next best one was strophanthus. It should be given in doses of five minims every four hours. Strychnine was a useful cardiac stimulant, but should not be given in large doses for any great length of time, as this was liable to be followed by exhaustion. Hydrothorax, either bilateral or unilateral, as a cause of difficult breathing was now and then overlooked. Even though the effusion were a passive one, aspiration would often favor its reabsorption. During convalescence, those who neglected cautious but regular and systematic exercise out doors were apt to do indifferently. When the lesion was the result of an extinct endocarditis instead of an ever-advancing cirrhosis, the outlook was correspondingly encouraging. It would be a wise precaution for every one who had begun to take the downward course after broken compensation to place himself under constant medical supervision, even though apparently well. It should be remembered that rupture of compensation was the beginning of the end, however long deferred by intelligent management.

Dr. C. F. Wainwright said that if the profession generally realized the necessity for making a diagnosis of the initial lesion, and then would properly treat it at that time, he believed the majority of acute inflammations of the valves would recover, and that there would be comparatively few cases of chronic valvular disease coming for treatment. He would take exception to the amount of treatment given by the author to the heart independently of the blood-vessels. He personally was of the opinion that if it were possible to restore compensation by directing attention to the general circulation, the heart would be protected for a greater length of time. By the use of heart stimulants the energy of the heart itself was taxed, and there was only a definite amount of such energy available. He understood the reader of the paper to say that he would give digitalis in all valvular lesions, but personally he believed the use of digitalis was very dangerous in the case of aortic insufficiency associated with anæmia of the brain. The physiological action of digitalis was to prolong the diastole and increase the anæmia. Broadbent had reported several cases occurring in his own experience in which sudden death followed the use of digitalis under such circumstances. No one who had not endeavored to make the diagnosis of valvular lesions by inspection and palpation alone had any idea of how extremely important and useful were these methods of examination.

Dr. Achilles Rose said that it was sometimes of more importance, in cases of heart disease, to examine the abdomen than to distinguish the fine points elicited by auscultation. Thus, whenever a splashing sound could be elicited it was evidence of atony of the stomach. Relief of the gastroptosia would often prove more serviceable to the patient with heart disease than would the administration of digitalis. By reducing the size of the belly the work of the heart was materially diminished.

Dr. Conner said there was one feature of the treatment of these cases of chronic valvular disease that he desired to emphasize, and that was the great importance of rest in bed. Osler was fond of taking a case of uncomplicated mitral stenosis and placing it in bed, and then allowing students to watch the benefit derived from this without any other treatment. At times, it was nothing less than amazing to note the degree of improvement resulting from enforced rest.

Dr. Burt, in closing the discussion, said that he recognized the danger of using digitalis in cases of aortic insufficiency and aortic obstruction. When it was used in such cases, the patient must be very closely watched.

Physicians' Club of Chicago.

At a meeting, held February 16, "Graft" was the subject for discussion. Mr. Clarence Darrow, a lawyer defined graft as "the effort of any human being to take from society or from another human being or animal more than he really gives to society in return." Great grafts are done inside the law. The wise grafter never undertakes to get something contrary to the law. He undertakes to fix the law so that he can get something according to the law. It is more profitable and safer. The cheap grafter, who does not understand his business, and does things by retail instead of wholesale, who has little voice in making or administering laws, undertakes to graft contrary to the law. Great capitalists graft inside the law. It is easier for them to choose their agents and their tools to fix the law the way they want it, and they get what they want without running the slightest possible risk. The grafter is a product of his environment. There is considerable grafting in the legal profession. Indirectly, that is what the legal profession is for, said Mr. Darrow. It is a business chosen by certain men because they think by pursuing it they can get more than they can by pursuing any other business they are familiar with. He said it speaks well for the medical profession that there are few doctors in Congress or in legislatures. Dr. Harold N. Moyer discussed medical graft. He said he has made inquiries from a large number of members of the profession, and has been unable to find anybody who knew anybody who grafted, or knew anything about graft, in the medical profession. He has found one or two men who said they knew of somebody else in the profession grafting, but upon running the inquiry down, he found it was false, and he received the word of the man himself to authenticate it. Dr. J. Clarence Webster asked about the Chicago surgeons in high places who contrive with country practitioners to send them patients. Such men existed, and one could put his fingers on them. It is not necessity that stimulates these men to carry out this nefarious practice, which is not only detrimental to their self-respect, but a temptation to weak brothers with whom they come in contact. Within the last month he saw a circular signed by a surgeon who is connected with one of the well-known hospitals of Chicago. This circular was sent around to various pysicians in Illinois and neighboring States, offering bribes for patients sent to him. He knows of the same

thing having been done by a professor in one of the best medical schools in a neighboring State. These men are not starving. They do not require to do that business, but they do it. What is the explanation? Not necessity, but deviltry—degeneration, and as long as men in high places do this, he said it is absolute folly to expect the struggling practitioners, who are in the position of being bribed, not to be bribed. Dr. Palmer Findley said the burden of medical graft falls upon the young physician and surgeon. He does not think any surgeon has to graft for bread and butter. Going out into a neighboring town two or three months ago to operate on a poor farmer's wife for a small fee, a physician, after the operation, showed him a card from an agent of a surgeon in Chicago, offering 50 per cent. commission. This practitioner also showed him a letter from a local surgeon who solicited cases for 25 per cent. commission. Another case was mentioned of a physician in the same town who had gone personally to the attending physician in a case in behalf of a Chicago surgeon, and had openly declared time and again that he was receiving a division of fees. The remedy should be the one President Roosevelt suggested for trusts—publicity—publicity through organizations, so that it will be impossible for men who are professors in leading medical schools and officers in medical societies to divide fees or give commissions. Mr. Wm. H. McSurely defined a grafter as one who allies or attaches himself to some outside interest, some interest apart from the main motive of his life, for the purpose of getting from that outside interest something that will be beneficial to the main motive of his life. He then spoke of lawyers and doctors as church grafters; the society grafters, etc. Dr. G. Frank Lydston spoke of the physician in politics and public affairs, saying that the doctor who devotes a portion of the years of his life to politics and to the public service is forever damned in the eyes of both the public and the medical profession. The reverse is true of the lawyer. In politics the lawyer attracts attention to himself. He said there were very few lawyers who rendered services in the interest of the public without salary, although this was frequently done by physicians.

College of Physicians of Philadelphia, Section on General Medicine.

At a stated meeting, held February 8, Dr. W. Egbert Robinson presented a patient with chronic polycythemic cyanosis, occurring in a Russian, fifty years old, occupied as a teacher of language, with a history of generous use of alcohol and tobacco, but a denial of venereal infection. In addition to the cyanosis and the increased number of red blood cells—above nine million—spleen and liver had become markedly enlarged within a relatively short time. The number of leucocytes was increased, but the hæmoglobin-percentage was diminished. The question was raised as to the advisability of splenectomy. Dr. Wm. G. Spiller presented a communication entitled "Remarks on the Uncinate Group of Fits, and on Extensive Hemorrhage Occurring in Epilepsy." Hughlings Jackson has described cases in which movements of mastication and of swallowing occur, or vision becomes obscured, or a sense of taste or smell appears, or a dream-like state develops, sometimes followed later on by convulsive manifestations, and to which he has given the designation uncinate group of fits. Dr. Spiller related a series of cases of this kind, and also one of epilepsy in which there was extensive subcutaneous hemorrhage, and still another in which apparently cerebral hemorrhage or thrombosis occurred as a sequence of the epileptic status rather than as a cause. Drs. David Riesman and Francis T. Stewart presented a communication entitled "Persistent Sialorrhea Following Herniotomy," reporting the case of a man in whom such an association appeared on the day following operation and had persisted for many weeks, despite varied treatment. The condition was considered reflex. Other varieties of sialorrhea are local, as from inflammations in or about the mouth; toxic, as from mercury, pilocarpine, iodine; psychic, as from the thought of food; vicarious, as in the presence of disease of the pancreas. Dr. James M. Anders read a paper entitled "The Relation of Typhoid Fever to Tuberculosis," in the course of which he related six cases from various sources, including two under his observation, in which the two diseases were asociated and each appearing to exert a modifying influence upon the other.

Philadelphia Pediatric Society.

At a stated meeting, held February 9, Dr. Theodore LeBoutillier reported a case of scurvy, occurring in a child following the substitution of barley-water and the like for milk in the course of treatment for gastrointestinal disturbance. Improvement set in at once after regulation of the diet, with a proper milk-mixture and vegetable juices. Dr. G. G. Davis exhibited a new club-foot stretcher for inveterate cases of club-foot. This consists of two heavy arms of metal jointed at one extremity and provided with plates to receive the heel and the ball of the foot, the pressure being applied from above to the arch of the instep. Dr. James K. Young exhibited a portable appliance for the application of plaster casts. This consists of a frame constituted of two parallel longitudinal and transverse bars each that can be detached and joined together, and between the transverse portions of which a strip of muslin is stretched, the subject being received in the prone attitude upon the latter. Drs. S. McC. Hamill and F. T. Stewart exhibited a specimen of intestinal adhesion, probably of traumatic origin. The patient had been exhibited at a previous meeting, and gave a history of an injury to the right loin, followed by the development of a swelling in this situation, presenting variations in size. The mass was believed to be an enlarged and displaced kidney. Subsequently, blood was passed repeatedly by the bowel, and suspicion of malignant disease of the intestine was aroused. Operation was undertaken and a mass of adhesions found in the right hypochondrium. An apparent constriction of the bowel at this point was excised and end-to-end union undertaken. The child, however, failed to rally, and death resulted. On examination of the specimen obtained through the wound of operation, it was found that the ascending and transverse colon had been adherent and connected by a communication of opening. Dr. Edwin E. Graham reported a case of intussusception, with remarks on the treatment. The patient was a child with a history of constipation from birth, for the relief of which laxatives and enemata had been repeatedly employed. Symptoms of intussusception of the bowel developing, a tumor was detected on introducing a finger into the rectum. Irrigation of the bowel was practised and the tumor palpable through the anus disappeared, although the original symptoms persisted. The condition of the child becoming increasingly grave, operation was resorted to, the intussusception released, but the shock and other symptoms failed to yield and death resulted. On post-mortem examination, it was found that the intussusception had not recurred, and the conclusion was reached that death must have resulted from the shock and other attendant phenomena. Dr. S. McClintock Hamill read "The Report of the Milk Commission for the Year 1903." The milk from five dairies is being certified, as complying with the bacteriological and chemical requirements established by the commission. One dairy was dropped for non-compliance, and another withdrew voluntarily. The milk and cream are examined systematically for their bacterial content, their reaction and the percentage of proteids, fat and carbohydrates, and when deemed necessary inspection of the dairy and the herd is made without previous notice. The good results

of the work are shown in the constancy with which the requirements of the commission are attained by those attempting do so.

Pathological Society of Philadelphia.

At a stated meeting, held February 11, Dr. W. B. Stanton exhibited a specimen of aneurysm of the arch of the aorta mistaken clinically for pulmonary tuberculosis. The patient presented cough, expectoration, wasting, dulness at the apices of the lungs and moist râles, death taking place from heart-failure, but the autopsy disclosed two large aneurysms of the aorta, one of which was of extraordinary size, with thick walls and lined by a considerable amount of laminated clot. Drs. C. W. Burr and D. J. McCarthy exhibited a specimen of multiple thrombotic softening with tumor-infiltration of the brain. The patient admitted syphilis and gave a history of repeated attacks of loss of consciousness. During life he presented right hemiplegia with word-blindness and from time to time he had attacks of more or less general convulsions. After death several areas of softening were found in brain and cerebellum, while the left cerebral hemisphere was enlarged and of increased consistency, and it was believed to be the seat of an infiltrating subcortical neoplasm. Dr. McCarthy exhibited also a specimen of probable tuberculoma of the skull from a girl who in early life had a fall, followed by convulsions, and later by ataxic gait, nystagmus and loss of vision, with secondary optic atrophy. After death a tumor apparently in part caseous, in part calcareous, was found in the left cerebellar fossa and causing pressure-softening of the cerebellum. Dr. R. C. Rosenberger read a paper entitled "Some Recent Contributions to the Study of Serum Reactions." Among the diseases named in which the agglutination and sedimentation of the bacilli causative of various diseases were induced by blood or blood-serum from patients suffering from the respective diseases were typhoid fever, paratyphoid fever, pneumonia, tuberculosis, dysentery, cholera, tetanus, relapsing fever, plague, Malta fever, and affections due to colon-bacilli and to streptococci. Dr. Robert N. Willson, Jr., and Dr. Coca exhibited a section of liver and one of spleen from the body of a man who during life presented a history, symptoms, and physical signs of pneumonia, but in which post-mortem examination revealed the existence of acute miliary tuberculosis. Dr. Alfred Stengel exhibited a large number of urinary calculi passed by a man who for many years had presented symptoms suggestive of renal calculi, but who only recently began passing the small globular concretions at the rate of about forty a day.

Cincinnati Research Society.

At a monthly meeting of the Cincinnati Research Society on February 18 a demonstration was given by Dr. S. P. Kramer, in which he attempted to prove the "Nature of the *X*-ray." He stated at the outset that he was working on the assumption, which was as yet purely hypothetical, that the ray was a bombardment of five metallic particles. He said that facts pointing in this direction were the deposit which occurred on the inner surface of the tube after use, the fact that as the density of a material increased its penetrability to the *x*-ray decreased, the fact that a vane placed between the electrodes in the Crooks' tube was made to resolve by the ray playing upon it, the fact that the *x*-ray burn was different in character from the ordinary burn and acted as if some noxious agent were deposited in the tissues preventing healing. In support of this hypothesis he himself had demonstrated that the tube loses weight by continuous use (.0011 in one hour), also that the negative which has been exposed to the *x*-ray is not rendered soluble by $Fe_2 Cl_6$ as is the negative of the ordinary photograph. He also pointed out that a Leyden jar so held that the electric spark just failing to discharge was made to discharge by turning the *x*-ray upon it. Dr. M. L. Heidingsfeld added to these demonstrations that he had found by chemical examination that the deposit on the inner surface of the tube contained platinum.

A paper was then read by Dr. M. L. Heidingsfeld entitled "Nævus Linearis." He reported three cases, and called attention to the unilateral character of the disease and the great diversity of the pathological appearances at different times, and often in the same case. He showed photographs of the cases, together with photomicrographs. Under the microscope some of the lesions resembled the ordinary clavus, others the venereal wart, and still others sarcoma. In one case a nodule had been removed in the belief that it had become sarcomatous.

Cincinnati Academy of Medicine.

At a regular meeting of the academy, held February 15, a paper was read by Dr. F. D. Phinney entitled "Some Points on the Pathology and Routine Examination of the Ocular Muscles." He said in brief that greater care should be exercised in the investigation of the etiology of the ocular deviations, for only by a correct understanding as to the muscle or function primarily at fault can we hope for any degree of success in our therapeusis. While many deviations may primarily be due to a purely muscular abnormality, the greater number are dependent upon some derangement of the convergent or divergent function. An esophoria may not only be due to a convergence excess but to a divergence insufficiency, or we may find either one of these conditions engrafted upon the other. In fact, it is the general rule for a deviation to become generalized throughout the whole field, so, that in cases in which asthenopic symptoms are pronounced for one distance only, we later find them manifested both for distance and near. The problem before us is to determine in these complicated cases which was the primary affection. Tests should be made both for distance and near, and several different tests should be employed so as to check off results and avoid any additional sources of error. The screen and parallax tests seem so far to give satisfactory results, especially when used in conjunction with the Maddox rod and phorometer. The usual custom of simply testing with prisms, base out or base in, must give unsatisfactory results if we allow ourselves to depend on this alone. The prism convergence or ability to overcome prisms base out is by no means a constant quantity and may vary considerably in the same individual at different times. For near it is difficult to see what real information this test can give. While many deviations of considerable amount appear to cause but little trouble, we frequently find that those of very minor degree give rise to marked symptoms of asthenopia.

After the discussion of this paper a paper was read by Dr. C. W. Tangeman entitled "Purulent Conjunctivitis." He spoke of the immense importance of this disease and of the large percentage of the blind of the world for which it was responsible. He gave a brief outline of the etiology and symptomatology and spoke of how often, unless very carefully treated, the disease went on to sloughing of the cornea and destruction of the eye. He spoke of the difficulty in severe cases of everting the lids, especially in the new-born child, and of the impossibility of cleansing the eye properly unless this were accomplished. The main object of the paper, it was stated, was to speak of the great utility in this disease of cleanliness and of some of the newer silver solutions. In speaking of the Credé method of prophylaxis in the new-born, he said that in his estimation the after-flushing of the conjunctival sac with salt solution was of greater service than the use of nitrate of silver, and that if he were limited to one agent for the treatment of the disease his choice would be water in sufficient quantity skilfully applied. He then spoke of

the use of the nitrate of silver, and stated that it caused a coagulation of the surface of the conjunctiva as soon as it came in contact with it, and in this way was prevented from penetrating to a sufficient depth to reach the gonococci in the tissues. He also said that it was a dangerous remedy in the presence of corneal ulceration. The use of one of the newer organic silver salts was preferable.

Dr. D. T. Vail said in discussion that he had always found the nitrate of silver satisfactory. Dr. Louis Stricker said that he had used other silver solutions in preference to the nitrate. Dr. J. M. Withrow spoke of the value of teaching the routine cleansing of the eyes of the new-born child, and told of a case in his practice in which the nurse was so well trained that she used the Credé method after delivery by cæsarean section.

New Instruments.

RADIUM RECEPTACLES FOR THE STOMACH, ŒSOPHAGUS, AND RECTUM.*

By MAX EINHORN, M.D.,
NEW YORK.
PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

X-rays have been found to be of great value in the treatment of cancer of the superficial organs. An attempt to use these rays in malignant neoplasms of the digestive tract has shown itself to be of no value, probably because the Crookes' tube cannot be applied to the organ directly. Since Curie has lately discovered the remarkable properties of radium, and since even favorable results have been reported from the use of this agent in superficial affections, the idea naturally presented itself to try it in malignant diseases of the digestive apparatus.

To accomplish this, I have constructed radium receptacles for the stomach, œsophagus, and rectum. These apparatuses allow the radium to be applied locally as near as possible to the seat of the disease. The effect will thus probably be most pronounced.

The radium receptacle† for the stomach consists of a glass capsule that can be screwed apart, the upper part of which is provided with an opening for the attachment of a silk thread (Fig. 1). The radium flask is inserted into this capsule, the latter is screwed together, the silk thread attached and knotted. The length of the latter must be about 75 cm. There should be knots at 40, 50, and 63 cm. The first knot (at 40 cm.) indicates the distance of the cardia from the lips, the second (50 cm.) how far the capsule should be distant from the cardia, and the third (63 cm.) the distance from the mouth to the lobe of the ear.

The method for introducing the radium capsule is the same as that for the introduction of the stomach bucket.

The patient swallows the radium capsule on an empty stomach, after it has been inserted into the pharynx by the physician, and drinks a glass of water. The capsule is allowed to project about 10 cm. beyond the cardia, *i.e.* the length of thread from the lips to the capsule should be about 50 cm., and the thread is tied to the ear.

The radium is left in the stomach for about one hour, and then the receptacle is removed. This is done in the following manner: The thread is removed from the ear and the capsule is pulled up. We first encounter a slight resistance at the cardia, which must be overcome by gentle traction. The next point of resistance is met with where the larynx presses upon the œsophagus. Forced action would hurt the patient; he is therefore told to swallow, and during this act the instrument is withdrawn.

The receptacles for the œsophagus and rectum show a similar construction. They consist of capsules that may be screwed apart, made of glass or aluminum (or any material which does not prevent the radium radiations to any great extent) (Fig. 2). On the cover is an elevation provided with a screw-thread, which is destined to receive a bougie. They are used as follows: After the radium has been inserted into the olive, and the latter been screwed together, the bougie is attached and the instrument introduced into the œsophagus (or rectum). It is self-understood that it is introduced so far that it lies just at the point affected. It is allowed to remain one-half to one hour, according to the amount of radioactivity.

Fig. 1.—Radium Receptacle for the Stomach.

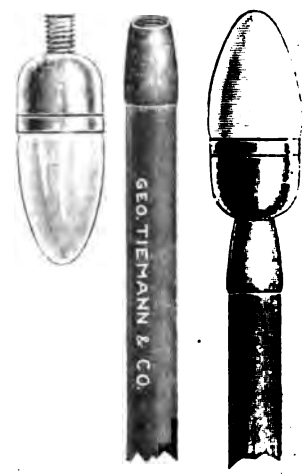

Fig. 2.—Radium Receptacle for the Œsophagus and Rectum.

Regarding the results of these methods not much can be said as yet, since they must be tried on an extensive clinical material. I have tried radium‡ in the stomach receptacle in a patient for three weeks with apparently good result; the tumor seems to have diminished in size and the pains have considerably decreased.

After having gained further experience I intend to report again on this subject.

*Paper read and apparatus demonstrated on January 22, 1904, at a meeting of the Society of German Physicians of New York.

†Those receptacles for the stomach, œsophagus, and rectum were made for me by Stohlmann, Pfarre & Co., New York.

‡The radium was of 7,000 activity (the quantity being 0.25 gram.).

Epidemic Catarrh on Shipboard.—Seventy-one swabs from the nose and throat were taken showing staphylococcic and streptococcic in eight cases which were cultivated. The author concludes there was a contagious factor in the attack. Most of the cases had a respiratory catarrh. Urine negative. The blood showed a leucocytosis. The cultures showed invasion by cocci. The cases of pyæmic fever and arthralgia are thus explained. A medium-sized diplococcus occurring in groups, tetrads, or chains was found so constantly that the author attributes considerable influence to it. Pfeiffer's influenza bacillus was not noted. The enlarged cervical glands indicated a protective reaction. Ulcerations and neucrotic patches in the throat were probably due to leptothrix, streptothrix, and higher bacteria. Bad hygienic surroundings, such as overcrowding, poor ventilation, dampness, heat, and decomposing dirt were thought to be causative factors.—*Journal of the Association of Military Surgeons.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 27, 1904:

	Cases.	Deaths.
Measles	1239	18
Diphtheria and croup	368	57
Scarlet fever	452	32
Smallpox	...	...
Varicella	112	...
Tuberculosis	419	180
Typhoid fever	40	10
Cerebrospinal meningitis	...	...

An Early Symptom in Severe Cases of Perityphlitis.—Moszkowicz has collected seventeen cases of his own, and twenty-nine others in which the abdomen was opened for appendicitis within the first forty-eight hours. Out of these forty-six cases a free peritoneal exudate was present in twenty-seven, and it is probable that in other cases in which fibrin was found that operation a few hours earlier would have revealed a fluid exudate. The difficulty of recognizing the severe cases with diffuse suppuration sufficiently early to make operation successful is well known, and the author thinks that a careful examination of the abdomen for free fluid will often be of great diagnostic assistance.—*Münchener medizinische Wochenschrift.*

Ascending Renal Infection.—John A. Sampson presents the following conclusions: (1) The vesical part of the ureter changes under the various degrees of dilatation and of intravesical tension of the bladder, and in each of these conditions one may find special provision for guarding the lumen of the ureter and thus preventing a reflux of urine from the bladder into the ureter. Under all conditions of the bladder the direction of the current of urine from the kidney to the bladder is a constant factor in the prevention of ascending infection. In addition there are present: (a) In the distended bladder, the very oblique course of the ureter and the long ureteral valve, the lateral walls or labia of the ureteral orifice, and the mucosa of the ureter; (b) in the contracted bladder, the course of the ureter is less oblique, the ureteral valve is shorter, and these factors apparently play a less important part in the protection of the ureter, than they do in the distended bladder. On the other hand additional protection is afforded by a puckering of the ureteral orifice; the ureteral labia may come together, and the ureteral mucosa is thrown into folds. (2) The anatomical structure and physiological action of the ureters as well as clinical experience would indicate that the function of the ureters is not only to carry urine from the kidneys to the bladder, but also to prevent fluid from passing into the ureters from the bladder, and that under normal conditions it is impossible for the latter to take place. Cases have been reported which contradict this statement. The fact that an occasional case has been reported in which apparently a reflux has occurred, especially when nothing is known of the condition of the ureteral orifice in these instances, cannot be regarded sufficient evidence for supposing it may occur in all cases. (3) Organisms may be conveyed from the bladder to the kidney through various channels. The reflux of urine from the bladder into the ureters may be considered an etiological factor in the causation and maintenance of renal infection only when the intravesical part of the ureter is diseased, thus impairing its function, or when some ureteral abnormality exists. Other etiological factors of great importance in the causation of renal infection are an injured kidney, which presents a lowered local resistance, and general ill health of the patient, that is, lowered general resistance.—*Johns Hopkins Hospital Bulletin.*

The Vaginal Operation for Carcinoma of the Uterus.—Flaischlen reports the results obtained by him and Ruge on a series of private cases of carcinoma of the uterus operated by the vaginal route. These show a total percentage of cures of 34 per cent., or, including three patients who survived the operation from two and one-half to four years and then died of independent conditions, a percentage of over 40 per cent. of cures. Of the seventeen cases now living and well, twelve were operated over ten years and nine over thirteen years ago. Three cases have remained cured sixteen, seventeen, and eighteen years respectively. The diagnosis was always established by microscopical examination, and the results do much to confute those writers who consider the vaginal operation solely as a palliative measure.—*Zentralblatt für Gynäkologie*, Vol. 27, No. 52.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 27, 1904:

SECONDARY LAPAROTOMY.*

By H. C. COE, M.D.,
NEW YORK.

ALL of us who have served an apprenticeship in gynecological clinics have arrived at the conclusion that there is a wide difference between the word "cured," entered on a patient's discharge slip and her condition a few months, or years, after operation. After we had carried out the usual routine treatment for a long time in the out-door dispensary without results, and had then referred the woman to the hospital for operation with the confident assurance that she would be permanently relieved by operation, it used to be most disappointing to receive her back again no better than before, or even to find that her latter state was worse than the first. Doubtless we have often criticised the gentlemen who performed the operation and promised ourselves that if we ever occupied their positions we would do better. Our time has come; we have had our years of experience, with better technique and wider opportunities than our predecessors, yet we still furnish our quota of unsuccessful cases, and a new generation is viewing our work from the same critical standpoint. Our patients are "cured" so long as they remain under observation, but after that—what? I have ventured to touch on an old theme, not only because it is of practical interest to the youngest, as well as to the oldest of us, but because the last word has by no means been said. Doubtless secondary operations are much less frequent now than they were before the days of rigid asepsis and exact technique, when explorative incisions and incomplete abdominal sections were so common.

When we recall the ordinary complications of to-day before which the boldest surgeons used to recoil and close the abdomen, the explanation is self-evident. From their standpoint that was the wisest course, in view of the frightful mortality attending even simple ovariotomy, not to speak of the abscesses, herniæ, fistulæ, and other complications that were so common in patients who survived. The rôle of the silk ligature then used must not be forgotten.

With the lowering of the mortality there has also been the elimination of many of the conditions which retarded the convalescence and rendered miserable the after lives of those who recovered from the operation. But that we have still room for improvement is evidenced by the considerable number of patients who require a second laparotomy before they are restored to health. The reasons for this are two: The fact that more severe and complicated operations are now undertaken, involving the separation of extensive intestinal adhesions, the removal of infected organs and the denudation of large peritoneal areas; and also the general adoption of conservative methods in the treatment of diseases of the adnexa. Ventro- and vaginofixation may be mentioned as popular procedures which occasionally give rise to subsequent trouble. I wish to state at the outset that I cannot subscribe to the oft-repeated assertion of a skilful, but combative, surgeon in a neighboring city that the necessity for a second abdominal section always implies careless or imperfect work on the part of the former operator. If this were so, none of us (including the gentleman in question) would see salvation. Such a sweeping criticism ignores the anatomical processes which follow every abdominal operation.

I need not define my subject, as you, of course, understand by "secondary" laparotomy one undertaken several months, or years, after a previous section for the relief of symptoms that either were not relieved by the former operation, or have developed subsequently in consequence of new pathological processes, due to the lighting up of old foci of disease only partially removed, or to local condition not directly dependent on the former ones. These vary in importance from slight adhesions to virulent pus-collections attended with profound septic infection. Exudates, fistulæ, neoplasms of the ovaries and broad ligaments, ectopic gestation, subsequent disease of the uterus —all these conditions are familiar to those who have had occasion to reopen the abdomen. Even after hysterectomy the formation of a broad ligament cyst may necessitate a second laparotomy, as I have noted in four or five cases.

An extended consideration of the pathology of this subject, though of great interest, would lead us beyond the limits of this paper. The question of intrapelvic adhesions alone (which I have discussed elsewhere) would furnish material for a monograph; indeed it has quite an extensive literature, both experimental and clinical. As regards the etiology, it would be interesting to inquire how far gauze drainage is responsible for permanent adhesions. That a fair number of drainage cases are entirely cured is admitted, and it will be granted without argument that even after simple, aseptic sections adhesions may be unusually extensive, without any history of a subsequent attack of peritonitis. One experimenter has gone so far as to state that adhesions form whenever the abdominal cavity is opened. Clinical experience is opposed to this view. Equally difficult of explanation is the fact that in many instances in which large raw surfaces and infected stumps are left adhesions either do not form, or else they are so slight that they give rise to no distressing symptoms. It is sufficient to note that adhesions do occur in spite of the most painstaking efforts to prevent them.

Fistulæ, intestinal, vesical or ureteral, are most annoying complications of both abdominal and vaginal sections, especially when they develop late in consequence of ulceration of a wound of the viscus, which was either not recognized during the operation, or was regarded at the time as of little importance. Nature is usually kind to the patient, but

*Read before the Obstetric Section of the New York Academy of Medicine.

now and then a second operation is necessary for their repair.

Secondary pus foci may be an evidence of imperfect technique, unwise conservatism, or reinfection—not to mention infected ligatures and stumps, foreign bodies left in the cavity, etc. It may be safely assumed that they are less apt to follow radical operations, especially vaginal. Hernia I shall not consider here, though it belongs properly among the conditions which require a secondary operation, especially as it is so often complicated by omental and intestinal adhesions.

The development of neoplasms of the uterus, adnexa and broad ligaments after previous operations in which one or both ovaries have been removed, is so common as to require no comment, since it was noted by the early ovariotomists. How often has the surgeon spared an insignificant cystoma or fibroid to see it grow until its removal was required! And quite as often an ovary which appeared to be perfectly normal, has undergone cystic degeneration, or has become the seat of a large tumor. Or a tube has become occluded and formed a hydrosalpinx or tuboovarian cyst, or even a pyosalpinx has resulted from subsequent infection. Allusion has been made to the appearance of broad ligament cysts after removal of the uterus. Whether the growth of intrapelvic tumors is favored by the circulatory disturbances consequent on the ligation of the large vessels or not is uncertain, but the fact remains that they do develop rapidly from apparently healthy organs after the primary operation. Personal experience has led me to remove the opposite ovary, even though macroscopically healthy, when its fellow is the seat of papilloma, since I have found that the remaining one is usually affected later.

This leads us to consider the pathological changes which may follow modern conservative operations on the adnexa. I have discussed these elsewhere and shall refer you for details to a paper in the Transactions of the American Gynecological Society for 1898. The views then expressed have been amply sustained by my later experience, including about three hundred cases. I do not overstate when I say that in over 5 per cent. of these a secondary operation—abdominal or vaginal—has been necessary in order to relieve distressing symptoms, or to cure morbid conditions following the former operation. I have no doubt that this percentage would be higher if I could add cases operated upon again by other surgeons. The abdominal was preferred for conservative work, which I suppose my colleagues who are skilled in vaginal section will regard as the principal explanation of the poor results. I may add that I have invariably endeavored to preserve the function of menstruation whenever a portion of an ovary could be saved without actual risk to the patient, especially if it was her urgent request. The wisdom of this course I am beginning to doubt, I believe that it is better for the surgeon to be unhampered by any positive promise, since to keep it may be to jeopardize a woman's life and to render the operation practically valueless.

I am strongly averse to resection of the ovaries and tubes in pus cases, though I have left the ovaries, or portions of them (never the tubes), with gratifying results. The only way to treat a pus-tube is to exsect it entirely and to suture the uterine wound and broad ligament with continuous catgut. In the presence of subacute gonorrhœal (and above all streptococcus) infection resection of the tubes, as Landau has remarked, is a delusion, since the new ostia are surrounded by adhesions within a few hours, and there is no more chance of conception than there was before—in fact, he believes that if it were not for this conservative work of Nature fatal results would follow more frequently than they do. However, I am not discussing the pros and cons of ultra-conservatism, but the ultimate results. These are the cases in which the formation of fresh exudates, imprisonment of ovaries, fresh suppuration, etc., often necessitate subsequent radical work.

The most promising cases are often the most disappointing. I have noted elsewhere the various changes which a resected ovary may undergo, from complete cirrhosis and atrophy to cystoma, with resulting amenorrhœa or menorrhagia and metrorrhagia. In at least a dozen cases I have been obliged to remove the uterus for profuse hemorrhages which did not yield to repeated curettement, though before the ovaries were resected menstruation was normal. Serial sections of these uteri showed that the cause lay outside of the organ. Two troublesome cases of intestinal fistula (fortunately the only ones which I have had after laparotomy) followed conservative operations on the ovary. One healed spontaneously. The other—an aseptic case without rise of temperature—was cured by a secondary laparotomy, when I found that ulceration of the gut had occurred at its point of attachment to the remains of an ovary. I shall never forget how the patient reproached me for my well-meant attempt to patch up her ovaries instead of removing them entirely. Understand, I am not arguing against conservatism in abdominal surgery. The many distressing psychical disturbances, atrophy of the vagina, etc., following castration, would furnish sufficient reasons for practising it aside from the question of curing sterility. I merely wish to emphasize the fact that not a few of our secondary operations at the present time are performed upon patients whose ovaries and tubes have been treated conservatively.

From all that we know of the pathology of the ovary and the difficulty of deciding by a hasty mascroscopic examination what portion is normal and what diseased, I think that we can fairly raise this question: "In a doubtful case may it not be wiser to let an ovary alone if we do not feel justified in removing it?" With the question of fresh gonorrhœal or septic infection we are not directly concerned, provided that we have removed all the disease at the time of the first operation. That we do eliminate it by our preliminary curettement, and by the catheterization and irrigation of infected tubes is more than doubtful; at least this would appear from my experience at Bellevue.

The frequency with which we find a diseased and adherent appendix on reopening the abdomen, where it was presumably healthy at the time of the previous operation, furnishes a strong argument in favor of the routine custom of removing it whenever the abdomen is opened, at least if it shows any departure from the normal. It is not pleasant to feel that one has been more or less responsible for appendical complications through timidity or unwise conservatism.

The principal indication for a second operation is pain, either the same of which the patient previously complained, or a new form more severe than before. Dysmenorrhœa, menorrhagia, vesical irritation, gastrointestinal disturbances—each of these symptoms may be so severe as to require surgical relief; but pain is the one which usually makes the patient willing to submit to a second section. In my experience intestinal adhesions have been the most common cause of distressing

toms, varying in severity from obstinate ic irritation (often dependent on traction the stomach by an adherent omentum) testinal obstruction. The pain may be gen- or localized, and, as before stated, may be ly out of proportion to the pathological con- . The same applies to pelvic exudates and ices in the broad and sacrouterine ligaments. pose that it is due quite as much to the limi- of peristaltic movements as to pressure on ed nerves. It is difficult to explain why so severe in cases of filamentary adhesions, is sometimes strangely absent, when the nes are firmly matted together, as in ant disease. Doubtless the neurotic ele- is an important one. Painful stumps, the nment of ovaries and tubes, traction on ck of the bladder, contraction of the lumen rectum, stricture, and even complete occlu- the ureter—all these result from the presence pelvic adhesions, and all give rise to more distinctive pains.

menorrhœa may be marked in connection stic or cirrhotic changes following resection ovary, though I do not recall a case in which the sole indication for interference.

orrhages so profuse as actually to sap the of the patient not infrequently call for re- of the uterus, even when the latter is small rophied, and the curette shows no evidence se of the endometrium. I have met with enomenon in connection with atrophied and when no satisfactory explanation could en. This menorrhagia, or metrorrhagia, ntinue unchecked, without pain or other ms.

ation has been called to the effect of on the stomach as the result of pelvic ment of the omentum, leading to obstinate g and indigestion, symptoms which are es promptly relieved by separation of the s. This condition should be suspected ection with prolonged gastric disturbances g laparotomy.

gards the diagnosis of conditions indicating d operation, we may dismiss as self- those in which the presence of persistent herniæ, neoplasms, extensive exudates and t foci are readily recognized by inspection, manual examination, and shall dwell more rly upon the less obvious lesions, the exist- which must be inferred, rather than posi- tablished. In order to draw a correct infer- to the probable morbid condition, one should e exact nature of the former operation, and complete history of the patient subsequently. nately this is seldom possible in hospital , even in the case of one's own patients. the witty French skeptic said, "There is something agreeable to us in the misfor- of our friends," it is certainly unsafe for us because we have an opportunity to revise gue's abdominal work, because he may be to perform the same service for us at any

average Bellevue patient can furnish little information as to what was done by the operator, and unless she has been under nt in the out-door dispensary, it is almost ible to determine whether her condition on e is due to the persistence of former symp- r to the results of recent infection. All are with the "rounders" who drift about ne hospital to another, seeming actually to the prospect of a new surgical sensation. I have reopened the abdomen for the fourth, and recently for the fifth time. The latter patient was a true connoisseur, having tasted the surgical delights of Mt. Sinai, Roosevelt, and the New York Hospitals before reaching Bellevue. Doubtless after a short rest she will start on her rounds again.

The presence of intestinal adhesions may be inferred from a history of more or less constant colicky pains in the lower abdomen, especially if they are localized at the site of a resected ovary or tube. Fixation of the uterus and of the remaining ovary and tube serve to confirm this opinion. Examination under anæsthesia is advisable in doubtful cases, especially in neurotic subjects, though the result may be practically negative. Persistent pain may be a sufficient indication for explorative incision, however, even though nothing abnormal can be detected on examination.

The prognosis as to complete relief by a second operation should be guarded. It is unsafe to promise a cure when we never know beforehand exactly the condition which we may encounter at the operating table. This was illustrated in the case of a patient who, after two laparotomies (the first conservative) and a vaginal hysterectomy has been my *bête noir* for several years, never once admitting that she is the least bit better than she was before the first operation.

In operating for certain obvious conditions—neoplasms, persistent hemorrhage, etc.—we may confidently expect positive results. But when it is a question of separating dense adhesions, or dissecting out exudates, one must never forget that these may recur in spite of the most careful work. The patient is usually relieved, sometimes permanently. Operations for the cure of fistulæ are often so difficult and prolonged that even recovery may be doubtful, aside from the possibility of failure.

It is unnecessary to dwell upon the technique of secondary laparotomy. You will note that I have confined myself to abdominal section, though I grant that the vaginal route may be employed. For simple removal of the uterus and remains of the adnexa I would prefer it, but I cannot yet admit that adhesions above the pelvic brim can be thoroughly separated and raw surfaces sutured except through an abdominal incision. Every case of repeated laparotomy is, in a sense, a surgical experiment in which the operator's reputation is involved. Naturally he will make a prolonged search for the cause of the trouble. The surgeon can hardly be too radical at his second séance. Usually he now has the full coöperation of the patient, who does not hamper him with the request to spare this or that pelvic organ, but simply gives him *carte blanche* to "take out everything if necessary this time."

The man who discovers a sure method of preventing the reformation of adhesions will deserve our lasting gratitude. Various suggestions have been made, such as the covering of raw surfaces with peritoneal flaps, the application of powders and films, filling the abdominal cavity with saline solution, early catharsis—all these have been tried and found wanting. In the meantime one can only deal with each case according to the special conditions present, with an eye to the future, as well as the immediate, welfare of the patient. It is to be hoped that as our technique becomes more perfect and our experience greater the number of secondary operations will become practically insignificant, and "recovery" will be synonymous with "cure."

Though I have not considered the relative advantages of vaginal *vs.* abdominal section, I would be glad if this topic were taken up in the discussion. We are all agreed that pus is best evacuated per vaginam, and that pus-sacs are most safely removed through this route when practicable. Whatever may be our experience with, or our predilection for, the abdominal route, the admirable results obtained by Dr. Pryor in his radical work, and the no less successful conservative operations performed per vaginam by Drs. Goffe, Vineberg, and others furnish the strongest argument in favor of vaginal cœliotomy in skilled hands.

It is generally admitted that the medicine of the future will be largely prophylactic. Any method of operating within the abdominal cavity which is proven to be attended not only with the lowest mortality, but with the fewest complications necessitating a subsequent operation, is the one which we ought to adopt.

† 8 West Seventy-sixth Street.

DRY SUPERHEATED AIR IN THERAPEUTICS.*

By CLARENCE EDWARD SKINNER, M.D., LL.D.,
NEW HAVEN, CONN.
PHYSICIAN IN CHARGE OF THE NEWHOPE PRIVATE SANITARIUM, NEW HAVEN, CONN.

It is not my intention to discuss the technicalities of thermotherapy in this paper, but to bring broadly and comprehensively before your notice, a therapeutical agent which is but too little used at present, but which is destined in the future to become a very popular and a very important factor in the management of many disease processes. The clinical results derivable from its employment and the principles governing its scientific application, are as yet not widely known among the profession at large, but the systematic study of its remedial influences under varying pathological conditions, which has now extended over a period of some seven years, has resulted in the accumulation of data sufficient to rescue the employment of the agent from the uncertain mists of empiricism, and to place it to-day upon a firm basis of rational indication in a considerable number of diseased states.

In order that any agent may be intelligently considered with reference to the correction of a given pathological condition, it is first necessary that its influence upon physiological function should be known. There are two varieties of hot-air applications: one where only the part affected is treated and which is denominated the "Local treatment," and the other where the greater portion of the body surface is subjected to influence and which is denominated the "General" or "Body treatment." The physiological actions of these two varieties of applications differ from each other in degree and to a certain extent also in kind, and may be summarized as follows:

Local treatment: relief of circulatory stasis; increased blood supply to the part treated; increase in the nutritive processes of the part due to reflex stimulation of the trophic nerve centers; the withdrawal of a large amount of fluid from the part treated through perspiration induced; and an increase in the temperature of the part treated whereby the chemical reactions constituting local metabolism are facilitated, and an inhibitive influence upon the development of any pathogenic microorganisms that may be present, is secured.

Body treatment: first, an immediate and powerful stimulation of the vital physical signs; second, reflex stimulation of the function of all the organs and tissues of the body, resulting in, first, a de of elimination of urea and other excreta whi believe to be unequaled by that producible with other measure now known, and, second, an am of reconstructive activity which I believe at present time to be also in excess of that deri from the use of other agents.

For purposes of study, therefore, the pathol conditions to which thermotherapy is applicab a curative measure, would naturally group th selves into three classes:

First, those in which the essential primary p ogy is strictly local, and for the cure of whic local hot-air application is sufficient. As ill tions may be mentioned, sprains, local septic tion in its early stages, and many cases of rh tism.

Second, cases in which the essential p pathology is local, but in which resultant con in the organism at large have extended the c symptom complex, and for the relief of whi additional influences of the body treatment up general bodily functions must be invoked. septic infection with profound systemic toxa a good illustration of this class.

Third, the constitutional or diathetic dise which only the profoundly acting, reflex in of the body treatment upon the metabolic fu are of benefit. As illustrations may be me true gout, many cases of nervous prostrati called), Bright's disease of the kidneys, and a deformans.

To elucidate the principles which govern the cation of dry hot air to different disease pro and to exemplify the clinical results derivable from, we will consider briefly a case repre each of the above-mentioned categories.

A sprain is the most typical condition be in the first class. In this condition we have a ogy which is strictly local, and which is no ently capable of inducing secondary effects threaten the integrity of the organism at lar have simply a traumatic solution of contin volving the soft tissues about the affected accompanied by severe pain, and greater obliteration of function. The objects of tr are to relieve the pain, to hasten physiologica of the damaged structures, and, if the case is one, to secure absorption of exudate. Theo the physiological influences of the local hot-ai ment would be most exquisitely applicable he the following case will illustrate how far experience confirms the validity of the deduc

Mrs. R. H., aged sixty-three years. Pati slipped on a curbstone during the afternoon 26, 1900, spraining her left ankle. I was a see her in the evening, at which time severe bing pain was constantly present, a swelling the size of a butternut was evident just bel anterior to the external malleolus, and the in this region were so sensitive as to be intolerant of any but the gentlest manip She was unable to put her foot to the floor of the resultant excruciating exacerbation pain. A local hot-air treatment was admi at 450° F. for an hour, which entirely relie pain, and she was put to bed without any bi or other local treatment to the foot.

May 27, 11 A.M.: Patient had been free fro during the night, and slept well; the swelli diminished a good 50 per cent., and onl pressure upon the injured tissue elicited Stepping upon the injured member gave rise t

*Read at the fifty-fourth annual meeting of the American Medical Association, before the section on Materia Medica, Pharmacy, and Therapeutics.

and holding it suspended downward induced a throbbing ache. Another local hot-air treatment was administered at 485° F., for an hour. An elastic bandage was then applied about the ankle in such a way as to give support to the lacerated tissues and the patient allowed to be up and

y 27, 10 P.M.: Ankle had been entirely comfortable all day. Swelling had entirely disappeared, some tenderness upon deep pressure was still observable immediately below and anterior to the malleolus. Another, and the last, local hot-air treatment was administered, and directions given to apply the elastic bandage the next morning before leaving her bed. I saw her again during the morning of July 29, or sixty hours after the first hot-air treatment was administered, and all signs of the injury had entirely disappeared. The elastic support was discontinued and the incident was closed.

As a matter of fact if a sprain is gotten under treatment within four or five hours after the injury has been sustained, the pain will be relieved in half an hour and all traces of the trouble will frequently have disappeared within forty-eight hours. If the case has been neglected for two or three days, however, and exudate is present to any great extent, the complete removal of the disability will require from two to three weeks; the pain, however, is susceptible of the same immediate relief observable in the early cases. It is only necessary to compare the course of the remarking recovery from a sprain under ordinary treatment, which not infrequently covers a period of six or eight weeks, and those just detailed, in order to appreciate the immense advantages exhibited by dry hot air in the treatment of this condition.

Local septic infection with general systemic complication is the most typical condition exemplifying the second category. Here we have a primary local pathology, with the introduction into the general circulation directly dependent thereon, of a toxin, which through its depressing influence upon the central nervous system is not infrequently, sufficient to cause death. The objects of treatment would be, first, to rescue the central nervous system from the depression of the toxic bodies emanating from the local disease focus and present in the general circulation, and, second, to strengthen the vital resisting power of the tissues at the site of the microbic invasion, whereby they would be enabled to overcome the destructive factors by which they are being overwhelmed. As I have said, the body hot-air treatment exhibits the power to induce a profound acceleration of the eliminative function, and it exercises a powerfully stimulant influence upon the vital physiological processes, which attributes satisfy the first demands of the plan of treatment; and it stimulates the trophic nerve centers to a high degree of normal reconstructive activity, which satisfies the second demand of treatment.

In illustrating the clinical confirmation of these observations regarding the usefulness of dry hot air in the management of profound septic infection, I recorded the following case in a paper read before the Medical Society of the New York School of Physical Therapeutics this past winter, and the case is such a striking exemplification of the point that I will quote it in full from that paper:

"Mr. A. W. A., aged fifty-one years. Was admitted to the New York Hospital on the morning of January 8, 1902, with a traumatic amputation of the left foot at the ankle. The crushed member was attached to the leg merely by the lacerated posterior tissues. Patient, of course, was suffering considerably from shock. Amputation of the lower third of the leg was done by Dr. Francis Markoe that afternoon. Septic infection, however, declared itself three days after the injury. On January 12 it was noticed that the knee was swollen, on January 15 pus began to discharge from the wound, and in spite of the utmost care, the condition increased in gravity until January 23, fifteen days after the original injury. At this time the leg up to the knee and somewhat above this joint was enormously swollen, the tissues of the stump were sloughing in places, and the patient's general condition was one of extreme prostration. In short, he presented a typical picture of the severest form of blood poisoning, except that streptococci had not been found in the blood. It was decided to amputate the infected member above the knee as a forlorn hope. This was done by Dr. Frank Hartley on the evening of January 23, at the middle of the thigh. The patient rallied very well from the operation and the next morning was given a body hot-air treatment.

During the time intervening between January 24, the day of the second operation, and March 8, the day of his discharge from the hospital, the patient received thirteen body treatments, the greater number of which, of course, were given during the two weeks immediately succeeding the amputation of the thigh. His general condition began to show slight evidences of benefit at once in the way of increased comfort, ability to sleep, and improvement in the vital signs, and he continued to gain slowly but steadily, until by the fifth of February his improvement had become so manifest as to justify a prognosis of recovery with a moderate degree of certainty. From this date on, his improvement was entirely satisfactory, and to-day his general condition is as good as it has ever been in his life before, and he weighs as much within one pound without his leg as he ever did with it.

In order to indicate the gravity of the case I will say here that it was the unanimous opinion of the physicians who saw him that neither the operation nor any ordinary therapeutical measure would save the patient's life. The fact also that slight evidences of tissue disintegration appeared in the wound three days after the second operation, is indicative of the fact that the operation and therapeutical measures other than hot air would not have sufficed to secure a successful termination."

In diseases belonging in the third category we encounter disordered metabolism, which results in, first, impairment of the developmental processes concerned in the formation of new tissues and organic secretions, and, second, the presence of suboxidation products in the circulation which are depressing to the nervous structures with which they are more or less constantly brought in contact. The prime objects of treatment, then, would be first, to accelerate elimination of the suboxidation products, either by direct excretion, or by inducing an increase in the body of oxidation reactions; and second, to apply a corrective influence to the perverted metabolic processes. The following case illustrates in what degree dry hot air body treatments may be expected to prove useful in the management of many of these cases.

Mrs. C. E., aged forty-six years, was admitted to the sanitarium for treatment, September 11, 1901. Nine months previously she had been attacked by a profound nervous prostration, accompanied by digestive disturbances, constipation, and inability to sleep. Her symptoms increased in severity during the following month, when she was compelled by actual muscular weakness to take to her bed, where she had remained ever since. She had had good medical advice during this period. At the

time of admission her condition was as follows: Height 5 feet, 5½ inches, weight, 76¾ pounds, as compared with 115 pounds when she was first taken ill. She was unable to take any but the lightest of nourishments without suffering from severe gastric distress, and severe intestinal indigestion was constantly present. Was obstinately constipated. So weak physically that she could not sit up in a chair long enough to have her bed made. Patellar reflexes slightly exaggerated but sensory phenomena normal. Mental condition normal, attitude generally courageous, but the steady increase in physical weakness, and the severity of the symptomatology had begun to tinge her naturally cheerful disposition with melancholy. She was sleeping fairly well. The menstrual function had been absent for the past eight months. The only abnormality betrayed by the urinary examination was an increase in the quantity of phosphates present. Absolutely no pathological conditions were discoverable by physical examination. The patient was evidently simply starving to death because of inefficiency of the digestive and assimilative functions, probably due to impairment of the nerve centers governing these functions, and as her menses had been absent for the previous eight months, I considered that the cause of impairment was probably climacteric in nature. The treatment administered was as follows: a diet of milk, eggs, and cereals; salines *pro re nata* for the constipation; a body hot-air treatment twice weekly; galvanization of the brain and spinal cord twice weekly; and general static electrification once a day. The first body treatment produced a long refreshing sleep the night following, and the next day her indigestion, both gastric and intestinal, was markedly diminished.

At the end of the first week these symptoms were so much lessened that her diet was expanded to include meat and vegetables once a day. Her weight had increased to 81½ pounds. She was sitting up in a chair each day, and expressed herself as feeling "splendid." A week later she felt well enough, and was allowed, to take a short trolley ride in the care of a companion. At the end of a month from the time of her admission she was allowed to go home for two weeks, after which she returned for a two weeks' resumption of the same treatment. At the expiration of this period, November 11, 1901, her weight had increased to 94 pounds, and she was eating and sleeping, and feeling splendidly. Her melancholy tendency had entirely disappeared,and she resumed some of her household duties.

She returned for another and a final two weeks' course of treatment on January 7, 1902. In the interval preceding she had continuously improved in every way. She was discharged from the sanitarium on January 21, 1902, the only remaining evidences of the trouble being a slight tendency to constipation which was readily controlled by an occasional pill consisting of aloin, strychnine, and belladonna. During her last week of treatment she expressed herself as feeling as well as she ever had in her life, and on her return home resumed full charge of her household duties, which she has continued ever since. I have seen her at intervals since, the last time being one month ago, and she informed me that she has had no signs of a return of the condition, and that she is, and has been, as well as she ever was except for a persistence of the constipation, which necessitates the frequent use of laxatives. Her present weight is 111½ pounds.

The time allotted me is too short to admit of any discussion upon apparatus or administrative technique. I shall, therefore, have to confine myself to saying in this connection, that the difference between an efficient apparatus and a proper and thorough application of the agent, and the reverse, will quently constitute the difference between succes failure in clinical results, and in direct proportio the prominence with which this fact is endowe the mind of the prescriber of hot-air therapy, wil benefit accruing to the patient be pronounce cannot feel satisfied to close this paper, how without referring briefly, to one prevalent er the popular conception of the *modus operandi* o curative power of dry hot air, and to one crit of the agent, which is just about as prevalent.

The error consists in the belief that the me produces its effects merely through the induct integumental hyperæmia, and toxin eliminati represented by the induction of profuse perspir This has led to applying the agent at temper only sufficiently high to produce sweating—t from 200° F. to 250° F. By this means elimi has been secured, and very effective elimi too, but that is all. Now to obtain the best a permanent curative influences of dry hot a must not only induce elimination, but we mu supplement and perpetuate, as far as possib advantage dependent thereon, by augmenti trophic reconstructive functions whereby w increase the patient's constitutional resistan effective stimulation of these processes is no ble unless the higher temperatures, from 300 400° F. are used.

The criticism is that the curative results o by its use are not *permanent*. This impre based upon the belief that hot air is only a pa measure, like a dose of morphine in painful tions for instance, and would never be entert the profound influences upon physiological f which we have been discussing, were taken in sideration. This belief was probably eng by the observation that cases of rheumatism with hot air *alone* frequently *did* "come bac this merely means that the disease was no because the thermal agent was not prope ported, and neither hot air nor any other agent can be expected to do alone what it w combined with proper adjuncts. The adv exhibited by hot air consist in its power to plish, either alone or in combination with agents, that which it is impossible for any combination of agents to accomplish without of hot air.

Another fact bearing upon this criticism when we have carried a patient through an att pneumonia, typhoid fever, rheumatism, or any disease except when the etiological factor ha removed surgically, we cannot assure him t will never have the disease again, no matter curative agents we have employed. We can c certain that the one attack has been extingu If appropriate environmental and constitut conditions again obtain he will surely have to su another attack, no matter how perfect may have his health in the meantime. When men no l contend with conditions which engender habi life that are inconsistent with their perfect phy health, then, and not till then, shall we be imm from repeated attacks of disease, and when millennium has arrived, dry hot air and every remedial agent will have retired to the oblivi complete desuetude.

In conclusion, permit me to say that the k the successful and satisfactory employment of dr air in the treatment of disease consists in bear mind that the agent is simply a rational therape measure, exhibiting a known and constant p ological action, which furnishes a logical basis which to consider its application to a given case

case in question presents a known pathology. It will, alone and unaided, cure some disease processes; others will require that additional agents be combined with it; and in still others all the curative resources at our command will not suffice to effect the patient's recovery. It exhibits in a marked degree the capacity to increase our power to overcome pathological conditions, and because of this, and the effectiveness of its influence in many situations unmanageable with other remedial measures, it is entitled to a prominent rank in the therapeutics of to-day.

STRANGULATED HERNIA.*

By JOHN F. ERDMANN, M.D.,
NEW YORK.
CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

I REGRET that a presentation of the relative frequency of strangulation in hernias is an impossible feature in this paper, and therefore present a consideration of fifty-eight cases of inguinal, femoral, umbilical, and ventral hernias operated upon by me for strangulation during a period of about eight years. These cases have been selected for the reason that they are the only ones operated upon in this period of time, of which I have complete records.

Inguinal Hernia.—There were thirty-one cases of inguinal hernia, all occurring in males. This is rather interesting from the fact that inguinal hernias are not peculiar to the male sex, but common to both, Coley showing in his article, "Radical Cure for Hernia," in the *Annals of Surgery*, June, 1903, that out of nine hundred and thirty-seven cases of inguinal hernia operated upon by him in eleven years, one hundred and eighty-one occurred in females. Of the thirty-one cases, seventeen occurred on the right side, and fourteen on the left, making an almost equal distribution as to frequency of sides. In twenty-five cases the contents were reduced immediately after overcoming the strangulation. In two cases gut was excised, the ends anastomosed and the intestine returned in one; in the other the gangrenous gut was cut open and the apparently healthy gut brought into the wound to be left until complete sloughing had taken place. This was done because the patient's condition was deemed unfavorable to further interference. I am now of the opinion that should such a case again occur in my practice, I would devote the extra ten or fifteen minutes to excising and anastomosing the gut rather than run the risk of an exhausting intestinal fistula remaining for a period of time, and thereby subjecting the patient to a second operation, or possibly death by exhaustion, etc.

Twenty-six of these cases recovered, the five deaths occurring are assigned to the following causes:

I. A child five years old; obstruction, abdominal distension, condition grave; a small nodule in the right groin, said by parents to have been present without variation in size from birth. Abdominal section done through right rectus; palpation revealed a hernia; this was proven to be a typical Richter. The gut was gangrenous; an excision and Murphy button anastomosis was hurriedly done; patient died in two days.

II. Patient about twenty-seven years of age; right properitoneal hernia; gangrenous gut about twelve inches long, this was split open and healthy gut brought into the wound; patient died in a few days from exhaustion.

III. Patient forty-five years of age; left inguinosuperficialis; sigmoid in the sac; sugar in the urine; died of diabetic coma the second day following operation.

IV. Patient sixty-three years of age; left inguinosuperficialis; exceptionally large hernia; adhesions extensive, but operative procedure easy; patient doing nicely, all pointing to a recovery; death on third day from embolism.

V. Patient forty years of age; left inguinal hernia of several days' duration; very fat patient; septic peritonitis in forty-eight hours.

The site of strangulation in every one of these cases was at the external abdominal ring. This was also noted in Coley's seventeen cases reported in the *Annals of Surgery*, June, 1903.

Femoral Hernia.—There were nineteen cases of femoral hernia operated upon. Of these four were males and fifteen occurred in females. There were twelve on the right side and seven on the left. In three cases gut was excised, three, four, and five inches respectively. Two of the excision cases recovered, and one, a female, died in a few hours. She was in a very poor condition at the time of operation.

There was another case of death which is of such interest that I report it in full, as it brings in evidence that occasional possibility—the reduction of a strangulated hernia *en mass*.

Male, fifty-eight years old; obstruction marked for three days when seen by me; a small mass the size of a filbert in the left groin, which was diagnosed by me as a femoral hernia. Upon gentle manipulation the mass was reduced with a peculiar pop. I expressed myself at that time that the bare possibility of a reduction *en masse* had occurred, and left word with the physician in charge that in case the hiccough and vomiting did not cease in a few hours I was to be called, when I would do a laparotomy. I was not called again for forty-eight hours, the family physician having gone out of town immediately after the reduction had taken place, turning the case over to his assistant, and the latter not having explicit directions, paid no particular attention to the case. Upon the return to the city of the original attendant, he recognized that the condition had not improved but was aggravated. I was then called again and did an abdominal section and found a knuckle of gut in its peritoneal sac in the abdominal cavity strangulated, black in color, and very marked adhesions of all the small intestines. The gut was deemed viable; after having released many bands of adhesions, the patient's abdomen was closed. This was done under most unfavorable hygenic and aseptic surroundings. He died in three days from peritonitis. No autopsy.

In seventeen of these cases the contents were reduced immediately. In two, females, the question of viability of gut was so grave that I left the herniated portion upon the surface of the wound until the following day and then returned the gut, completing the operation successfully.

Umbilical Hernia.—There were six of this type of hernia, all females, the majority suffering from excessively fat abdominal walls. One death occurred in this series in a patient thirty-three years old, who suffered from a strangulation for two days. Upon operating, the contents of the sac were found to be returnable—death occurred in fifteen hours, apparently from shock.

One case was of extreme interest; a young woman of about thirty years who had been ill for about a week was brought to me from the country with a history of pain, hiccough, and distension for six or seven days. There was a non-reducible protrusion at the umbilicus. The skin over this tumor was red, and upon palpating, fluctuation was found to be present; her general condition was good; a slight movement had occurred four days before. Upon dissecting down upon the tumor, considerable pus, foul in odor, escaped; the ring was small an

*Read before the Medical Society of the Borough of the Bronx.

contained a bit of slough about the size of a ten-cent piece. Upon enlarging the opening and wiping out the pus, it was seen that the intestines were matted together, making a protective wall for the general peritoneal cavity. In the center of this space an intestinal perforation was observed. Further dissection of adhesions revealed the proximal and distal ends of the jejunum with slough at each end. Ten inches in all were excised and a suture anastomosis was made. The wound was drained for several days. She was discharged from our care at the end of the fourth week.

Ventral Hernia.—Two cases, one a male, the other a female, occurred in my practice in this period. The male was a negro with a hernia in the upper third of the median line that had been reducible up to within a few days before I saw him. At the time he came under my observation his condition was poor, and upon opening the sac, gangrenous, foul-smelling omentum was discovered bathed in pus; no walling off of the cavity existed, and a general peritonitis complicated the picture. Excision of the omentum in a healthy area was done; the peritoneal cavity was wiped as clean as possible; drainage, etc. Death resulted on the third day.

The case of the female was due to a post-operative hernia in the lower half of the median line. Her condition was such as to demand other than general anæsthesia, so subdural spinal cocainization, aided with a hypodermic of morphine, was employed. Twelve inches of her ileum was excised; Murphy button anastomosis and drainage for two days employed. At the end of this time her condition allowed of a complete repair of the post-operative hernia, under general anæsthesia. She was discharged within four weeks with a solid abdominal wall. No pain was felt whatever during the operation done under spinal anæsthesia, but the vomiting was of such projectile character as to interfere with our progress until seven minims of Magendi's sol. had been given hypodermically. After this the mural and intestinal work was done with a greater degree of comfort, at least mentally, than if a general anæsthetic had been given.

Anæsthesia.—There is no doubt in my mind as to which anæsthetic to use. If the patient has not been vomiting, and the general physical condition will allow, a general anæsthetic can be used. Should vomiting be a prominent symptom, then either local or spinal anæsthesia should be selected. I personally prefer using local anæsthesia in all instances of strangulation, as the danger of vomiting and inspiration is overcome. The shock of the operation is also lessened.

Reduction.—Should the condition of the gut be such as to cause any question to arise of its being returnable, no reason can possibly exist for not allowing the herniated gut to remain in the wound for a number of hours, after being anchored by lightly packing around the released ring sufficiently to prevent the spontaneous return of the gut, and at the same time not to prevent the flow of blood to and from the involved intestine. Should the intestine after six or eight hours show non-viability, the secondary operation of excision and radical cure can be proceeded with. This procedure was followed in two of my femoral cases. The intestine was left in the wound over night with most excellent results in both.

As to reduction of omentum when not gangrenous, I am at present returning it always, unless it be matted together by adhesions or hypertrophied. In excising the omentum, I never use the locked or chain ligature, as this procedure rolls the omentum in a mass just as a puckering string does in wearing apparel, etc. This makes reduction in some instances more difficult. This variety of ligation also seems to me to be far less secure than where we take up small sections and make individual ligations, thereby allowing the omentum when reduced to resume its spreading relationship to the intestines.

Excision of Intestine.—There were seven cases of excision, from three to ten inches excised in all cases; one not being anastomosed (the case of inguinal reported); the others were anastomosed in three instances by suture, with one death; and three by means of Murphy buttons, also with one death.

The youngest excision case occurred in a male five years of age, death occurring from general septic peritonitis which existed before the operation.

Of the excision cases, one was an umbilical, one was a ventral, two were inguinal, and three femoral. One of the inguinals, as stated above, was not anastomosed.

Age.—The youngest case was a male thirteen days old; left inguinal hernia; no anæsthetic; recovery. The oldest was a female eighty-six years old; femoral hernia; local anæsthesia; recovery.

Some interest was felt by me as to the occurrence by decades, and the following was the result in fifty-three cases in which the ages are recorded:

First decade	2	Second decade	4
Third decade	13	Fourth decade	10
Fifth decade	8	Sixth decade	11
Seventh decade	3	Eighth decade	2

Although possibly of no statistical benefit, the following represents the number of cases by months. It will be observed that although heat has the physiological reputation of relaxing tissues, that, in my experience, the month of August was the banner month for strangulations.

January	2	February	7
March	6	April	6
May	4	June	5
July	4	August	8
September	5	October	3
November	3	December	3

This peculiarity may be explained on the ground that the hot weather relaxes the rings more, and thereby allows more hernias to occur, or if present to enlarge; that incarceration or strangulation then takes place by reason of irritation in attempts at reduction causing the rings to contract.

Also that during the cold months the tissues are in a more tonic state of contraction, thereby preventing increase in size or in production when tendency exists.

Superficial Inguinal Hernia.—Hernia Superficialis Inguinalis occurred three times; all on the left side; all characteristically likened to the able description given by Moschowitz, MEDICAL RECORD, June 10, 1903, in which article he reports one case, and states that it is a rare condition, only fifteen cases having been previously reported. Coley reports five cases in his article on "Radical Cure" in the *Annals of Surgery*, June, 1903. In each of my cases there was a non-descended testicle; all were adults, all occurred upon the left side, the last being an enormous hernia in a rabbi sixty-three years of age. This type is one of the interstitial variety, and usually lies upon the superior surface of the aponeurosis of the external oblique, the protrusion usually extending upward and outward. In two of my cases the tumor invaded the region from the anterior superior spine to that below the external ring.

Diagnosis.—There is no intention on my part of entering into a review of the symptomatology of strangulated hernia, but I would most emphatically say that the earlier the textbooks and our teaching bodies drop the variety known as incarcerated hernia, and classify all acutely non-reducible hernias as operative or strangulated, although not adhering strictly to the definition of strangulation,

at just so soon will our mortality rate dimin-
h. I fully believe that the acute condition
own as incarceration is but the early stage of
angulation, and that attempts at reduction
thout operation result in sufficient amount of
itation to produce strangulation proper. Fre-
ently one is called to a case of hernia of an in-
inal variety that proves to the expert to be a fem-
l. This error in diagnosis need rarely be made if
e remembers that femorals, except large, are be-
Poupart's ligament, or are below, a line drawn
m the anterior superior spine of the iliac crest
the pubic spine or crest, and that all hernias
ve this line, except those rare cases of large
oral that ascend above Poupart's ligament
r their exit, are inguinal. Even this condition
femorals can be differentiated in the greater
mber of cases by the ability to displace the tumor
nward below the line of Poupart's ligament,
ing the region of the inguinal openings free
m a protrusion.

Taxis.—Although risking the reputation of "Too
ical," I would say that taxis should never be
a moment after the diagnosis of irreducibility
made. A careful anamnesis of the case will
ily point the finger of diagnosis in the proper
ction, and slight manipulation with a view
reduction will readily prove the irreducibility
the tumor. The case of femoral reduced *en*
sse, reported above under femoral hernias,
a very powerful lesson in the dangers accompany-
taxis.

Treatment.—Anæsthesia, local, spinal, or general,
conditions will allow—the exposure of the sac
ore relieving the strictured neck, prevents the
taneous reduction of the hernia in cases of
ll protrusion of intestine or a true Richter,
occurred in one case of mine, and thereby causing
to make a more extensive operation in the case,
to pass several sleepless nights awaiting the
ult of a case of reduction of an unseen condition
gut.

Should the gut be deemed questionable for
rn, the use of heat or keeping the intestine
a few hours in the operating wound is advised.
uld the viability then be beyond question,
cision and anastomosis with return of the gut is
be proceeded with. Should positive death of
gut be present, immediate excision and anasto-
sis should be done for reasons stated elsewhere
this article.

After reduction of the hernia we should do a
dical operation in all instances, as but a few more
nutes are required for this procedure.

The after care is simple in all these cases. A
e of temperature from one-half to one and one-
lf degrees is perfectly consistent for two or three
ys without pus or slough formation. At the
me time such cases should have the dressings
ken down occasionally so that proper attention
ay be given to the wound. As strangulated
rnia operations are usually emergency operations,
is my custom to use a bit of rubber tissue for
in drain for twenty-four to thirty-six hours. A
ovement of the bowels is sought for in all non-
cision cases the second day, light diet until the
mperature is normal. Excision cases, enemas
e used for the first week, and rectal alimentation
from four to six days, fluids by mouth after the
sixth day, and light diet after the tenth.

Complications.—In all ordinary operations, *i.e.*
those without excision of intestine, infection in the
wound due to inability to properly prepare the
tissues, is the first consideration.

Inspiration-Pneumonias occur due to vomiting under general anæsthesia, and therefore I would again recommend local anæsthesia in these cases. Death under anæsthesia from inspiring vomitus has been seen by me once, and recently I have seen the report of three cases.

Solitary Follicle Ulceration with perforation above the point of strangulation, *i.e.* in apparently healthy gut, one case reported by Dr. George E. Brewer (see *Annals of Surgery*, Vol. XXXI, page 259). This complication is ascribed by Koch and König to either intense traction on the mesentery which interferes with the blood supply, or to the fact that the accumulation of intestinal contents above the constriction distends the gut and assists with the impaired blood supply in producing the necrosis. When intestinal excision with anastomosis has been performed, peritonitis with death may occur. Again, a fistula forms before the tenth day as a result of either imperfect suturing or tearing out of stitches, or by imperfectly applied mechanical devices for anastomosis, as the button of Murphy, etc. Again, the excision may not have been done in perfectly viable gut, and a slough with fistula results. Fortunately the majority of these cases of fistula occurring after the fourth day recover spontaneously.

Barring all complications, the patient is allowed a head and back rest about the fourth day, and is permitted to be out of bed on the thirteenth or fourteenth day, wearing a spica with a pad of gauze over the site of the repaired wound for a week in inguinal and femoral hernias, while in abdominal they are allowed the head rest about the same time, and out of bed in three weeks with a snug-fitting binder.

SOME POINTS REGARDING THE EARLY DIAGNOSIS AND SOME NEW FEATURES IN THE TREATMENT OF PULMONARY TUBERCULOSIS.*

By W. FREUDENTHAL, M.D.,
NEW YORK.

THE subject of tuberculosis is such a difficult one and the questions to be investigated are so numerous that it takes the medical practitioners of the entire world to help solve it. In this country numerous researches are constantly being made. In fact, some of these that have been made in this country have been followed up abroad. Thus, for example, you will remember the painstaking and interesting researches of Dr. H. M. Biggs regarding the centralization of cases of tuberculosis in certain tenement-house districts. Romberg (*Archiv für klinische Medizin*, Bd. 76) investigated this matter for the City of Marburg and came to the same conclusion as did Biggs, viz., that in certain residences of the poorer classes tuberculosis prevails. Haedicke's investigations ("Über die Ausbreitung der Tuberkulose im Distrikte der Marburger Poliklinik," Inaug. Diss. Marburg, 1902) amounted to the same. But this is only apropos. I shall not discuss these questions, but limit myself to the diagnosis and treatment of pulmonary tuberculosis.

Before such a society as this, I need not mention all the details that assist us in making an early diagnosis. It seems to me, however, that in this connection two points have been neglected, one of which is the condition of the upper-air passages in incipient tuberculosis and the other the injection of the old tuberculin Koch.

Having practised laryngology for a good many years, I have examined for tuberculosis every case of simple laryngitis that did not yield to the ordinary

*Read before the Section on Medicine of the New York Academy of Medicine.

treatment. This often gave me gratifying results, in so far that pulmonary tuberculosis was recognized when nobody thought of it. I naturally looked also for tuberculosis in cases of chronic laryngitis and similar affections. Now, what specific conditions can we find in the upper-air passages in cases in which we suspect tuberculosis?

Beginning with the nose, I shall not here discuss the connection between nasal catarrh and pulmonary tuberculosis. That question has been thoroughly ventilated. But permit me to draw your attention to a paper by A. Alexander of Berlin (*Archiv für Laryngologie*, Bd. 14). This author studied the question of ozæna and found that among fifty such cases not less than twenty-two had consumption; the majority of these patients did not have the slightest idea that they were suffering from a pulmonary disorder. But ozæna is a comparatively rare affection and cannot be such a distinct causal factor in a disease so widely spread as tuberculosis. I consider, therefore, in this connection, my own investigations more important. They convinced me that a great number of those suffering from dry or atrophic rhinitis finally fall victims to tuberculosis. This was verified by my examinations of three hundred and forty inmates of the Bedford Sanatorium for Consumptives (Beiträge zur Klinik der Tuberkulose, Bd. II, and *New York Medical Journal*, 1903), to which I would like to draw the attention of those interested in this question. The great number of those who suffered from these dry and atrophic conditions in the nose was really surprising.

More directly pointing toward deeper lesions are often the appearances in the pharynx and larynx. Supposing we have a case with vague symptoms in which a diagnosis of phthisis cannot with certainty be made. If we look into the pharynx of such a person we often see the uvula as well as the fauces highly congested and red, only the parts of the velum on both sides of the uvula are of an extraordinary pale color. This anæmia, extending more or less over the whole soft palate, and including not infrequently the greater part of the hard palate, is so characteristic that we may in such a case strongly suspect tuberculosis. I have found these local symptoms so early that the appearance of the patient would not lead one to suspect the presence of consumption and yet the patient developed phthisis afterward. This anæmia, which was already well known to Mackenzie, Gottstein, and other early writers, seems to be the first expression of the malnutrition of the patient.

Perhaps more characteristic is the picture in the larynx. In people with a hacking, dry cough we often see the whole larynx congested, and only the epiglottis shows the same pale appearance as the mucous membrane of the velum. In some exceptions I even saw a few miliary tubercle on the epiglottis, and they appeared in cases in which, from an examination of the lungs, no diagnosis could be made. Sometimes we see, even at an early stage, pale, smooth swellings of the interarytenoid fold, but more often this whole neighborhood appears congested. Finally, if these signs are not present, it will be well to examine the larynx according to the method of Killian. Thus, in certain cases, we are enabled to see small erosions on the posterior wall of the larynx and on the arytenoids.. They naturally tend to strengthen our diagnosis still more.

But if all this should fail and we are still in doubt as to the diagnosis, one means is left to us to make it positive and that is the injection of the (old) tuberculin Koch. Here and there we are confronted with cases in which, by no other method, a differential diagnosis can be made, for example between tuber culosis and syphilis, or malignant tumor or *aneurys* Let me give you an example of the latter: gentleman, forty-four years of age, was sent to m for diagnostic purposes. He had been hoarse f six weeks, had had hæmoptysis several times, harassing cough, and the sputum, which was scant was even now streaked with blood. On and v he suffered from dyspnœa. There was dulne over the left lung, bronchial breathing, and coa râles. Besides there was a paralysis of the l vocal cord. While this last symptom immediate made me think of an aneurysm of the aorta, s the whole clinical picture pointed so strongly tuberculosis that I accepted that as the diagno The paralysis of the recurrent nerve could ea be explained by an enlarged tuberculou glands pre ing on it. Still, during the next four weeks of ob vation no bacilli were found, the skiagraph reveal nothing, as it mostly occurs in these early cases, pulse remaining the same (no arteriosclerosis) a no fever, but increased dyspnœa, etc. Thea decided to make a diagnostic injection of Tub culin Koch. I gave him first 2 mgr., then 5 m and finally 8 mgr. No reaction whatsoever hav occurred, I concluded that this particular case not one of tuberculosis, but of aortic aneury Two months later the correctness of this diagn was easily proved by auscultation and percussion

This was one instance in which tuberculin was dicated. But there occur as well other doub cases, and for these injections of tuberculin are t recommended. While I was for a long time doubt as to the results of these probatory injecti and always was afraid of the dangers connec with them, newer reports, especially those of Roe and later by Hammer, have induced me to try t again. Thus Roepke made probatory inject on 145 patients and only two gave negative sults. Dr. France-Clayburg* injected fifty-five mates of an insane asylum, with forty-five actions. Of these, twenty-nine came to post-mor examinations and all were found to be tubercul Of the others that did not react, five were autop and no tuberculosis was found.

In order to be impartial, I have to mention Professor Schüle had a fatal result after the se injection of ½ mgr. tuberculin. But this ca not at all clear to me. Schüle himself remarks there was no indication for the second inject since the patient had already reacted after the

Personally I have had only a very limited perience in thirty-one cases, six of which wer private practice, while the rest, twenty-five in n ber, occurred in hospital service. I cannot rec any unpleasant results. The initial dose gi ranged from ½ mgr. to 2 mgr.; if there was no reac the dose was increased to from 3 to 5 mgr., an rarer cases repeated with a final dose of 8–10 m Out of these thirty-one cases, fourteen reacted a the first injection, twelve after the second, and had no reaction whatsoever. I have seen t of the last cases about eight to ten months l and none had developed tuberculosis. I wo therefore suggest that these injections be t on a larger scale in order to get exact data fr observers all over the country.

The next point to be discussed is the tre ment of tuberculosis, and of that I shall m tion only one phase, viz., the treatment with so-called blue rays of light. The modern tren in the treatment of such cases is to send as man of these patients as possible into especially adapte sanatoria and have them treated there.

*Quoted after Roepke.

Now, we shall never be able to give the benefit of pure country air to half of the sufferers, not even, I am afraid, to one-tenth of them, and the question is—what to do with the great bulk of the others? The answer is simply to treat them at home and give them some equivalent for the sanatorium treatment. This is done principally by exposing the patients to the direct or indirect rays of the sun. Since, in our climate, we cannot rely upon the solar rays during the winter months, we have a substitute for them in the electric light.

According to the investigations of Moleschott and Fubini, Uffelmann, and many others, there can be no doubt that the influence of sunlight is very great in increasing oxidation and stimulating the metabolism. That this holds good also in regard to the electric light, and especially to certain rays, has been shown within the last ten years by careful and reliable observers. As early as 1855 Moleschott proved, through his original researches, that animals (frogs) give off $\frac{1}{12}$ to $\frac{1}{4}$ more carbonic acid gas in the light than in the dark. With this, naturally, the increase in oxidation goes hand in hand. In this respect the concentrated blue light (violet light) is even more effective than the sun (Strebel, Gebhardt, etc.). You will, perhaps, know that for years I have been using electric light as a therapeutic agent in tuberculosis and have grown more and more enthusiastic about it. While I have to adhere to the statements in my first publication and repeat that electric light is not an antidote for tuberculosis, I believe more to-day than before that it is an important factor in its treatment. Permit me to summarize my former experience by saying that electric light acted as an: (1) Anodyne in relieving pain. (2) Expectorant, the patients being able to remove thick clots of phlegm from the smaller bronchi. (3) It regulated the temperature (!!) for several hours afterward. (4) It worked beneficially on the metabolism. It can hardly be said to exert a *direct* germicidal effect on the tubercle bacilli in the lungs. Its effect is noticed first on the skin. The skin is an exceedingly important organ in the metabolic changes. By the use of the electric light the activity of the skin is immensely increased, and indirectly at the same time the deeper organs are stimulated to increased action. Now, we know that the effect of the electric light depends not only on its intensity, but more so on the quantity of oxygen present. We may perhaps correctly say: The more oxygen there is in the tissues, the better the effect of the electric light. *A priori*, we cannot expect a surplus of oxygen in the system of a consumptive, and it was my idea several years ago to bring more oxygen into the tissues of these patients. I made them, therefore, inhale oxygen each time before they were treated with the electric light. This worked quite well in a few cases, as, for example, in that of a colleague with tuberculosis of the tonsils, or in one case of rodent ulcer of the face in which I could apply the oxygen directly. But in deeper lesions no improvement over the simple electric-light treatment was seen, and I believe that in those patients oxygen did not reach these parts at all when inhaled. Another method had, therefore, to be applied, and that was CO_2. Its use seems to have been forgotten. At least, as far as I am aware, only Dr. A. Rose of this city uses it on a large scale.

Allow me to remind you of some old experiments by Claude Bernard. Claude Bernard found that volatiles introduced into the digestive tract through the venous blood are carried into the lungs, where they leave the body without producing poisonous effect. Bergeon used this principle for rectal injections of carbonic-acid gas for the treatment of tuberculosis and other diseases, and you all know the disappointment that afterward followed. The fact nevertheless remains that we can introduce into the system a good deal of CO_2 without running any risk of poisoning. It is carried into the alveoli of the lungs, from where, according to the laws of diffusion, it is set free. In other words, in a given time more than the normal quantity of carbonic-acid gas will pass upward, and this will cause *a counter-current of a proportionately increased quantity of oxygen*, and this is just the object in using the CO_2.

Besides, there is naturally an antagonism between carbonic-acid gas and tuberculosis, as some claim. Thus Hugo Weber of St. Johann-Saarbrücken believes that when large quantities of carbonic-acid gas are present in the lungs, no tuberculosis can develop. Thus people with emphysema or those suffering from heart trouble and consecutive venous stasis have a certain immunity against that disease. On the other hand, children born with a stenosis of the tricuspid valve invariably die of pulmonary phthisis, and they, as you know, receive only a small mass of the blood carrying CO_2.

These deductions of Weber's are surely interesting, and so far my experience makes me believe that there is a good deal in these theories. I therefore commenced the combined treatment of electric light and carbonic-acid gas over a year ago and have applied it so far in twenty-two cases. Seven of those cannot be counted, as they stopped treatment too soon to form an opinion. Of the remaining fifteen, which were all in the so-called second stage of the disease, eleven showed marked improvement. By this I mean an increase of the appetite, which in some cases was simply remarkable, better regulation of the bowels and less cough. I am not inclined to believe that the better appetite depended solely on the regulation of the bowels produced by the injection of CO_2, but would rather attribute this to the improved general metabolism. At any rate, neither the bowels nor the appetite could in these cases be improved by any other medicinal or dietetic treatment. That in these cases the patients gained more or less in weight will be easily understood. But we should not lay too much stress upon this point. The four other patients did not show any improvement.

In summing up my experience, which will be published more exhaustively later on, I will say that the addition of CO_2 to the treatment with the so-called blue rays of light, has so far given me encouraging results and promises more for the future. The light rays form to-day the focus around which most new discoveries are concentrated. Let us hope that they may also bring light into this darkest corner of pathology, viz., pulmonary tuberculosis.

1003 Madison Avenue.

Eclampsia and Vaginal Cæsarean Section.—Ashfeld believes that the view taken by some writers that the uterus must be emptied immediately in all cases of eclampsia is extreme, and that a more rational course is to resort to less radical measures first and observe their effect on the disease. Chief among these is the hot pack, which nearly always produces a prompt and marked change for the better, and often is followed by spontaneous dilatation of the cervix. The metreurynter is greatly to be preferred to the Bossi dilator, and vaginal cæsarean section is indicated only in the rarest cases.—*Zentralblatt für Gynäkologie*, Vol. 27, No. 52.

THE RELATION OF PHYSICAL DEFECTS TO MENTAL DEVELOPMENT.

By GEORGE STOCKTON, M.D.,
COLUMBUS, OHIO.

SUPERINTENDENT COLUMBUS STATE HOSPITAL; MEMBER AMERICAN MEDICAL ASSOCIATION, OHIO STATE MEDICAL SOCIETY, COLUMBUS ACADEMY OF MEDICINE; LECTURER ON PSYCHIATRY, OHIO MEDICAL UNIVERSITY, ETC.

THIS is a subject of wide scope and I can only hope to mention the most important of the physical defects having a bearing upon the mental development.

Obviously the most common cause affecting mental development is heredity. Heredity has been defined as that peculiar property of an organism which transmits to its offspring the characteristics of its progenitors. It has been compared to a mirror reflecting from one generation to another the grace, beauty and strength, or else the coarse, ugly, and defective features of the one standing before it.

The doctrine of heredity is especially manifested in psychiatry. Indirect heredity is heredity by transformation from other neuropsychic diseases, and is more common, but of less consequence, than direct heredity. A diseased nervous system is not capable of resisting any unusual strain put upon it; the result is a neuropathic disposition, with a tendency to yield to adverse influences. Certain diatheses are propagated from parents to offspring; thus epilepsy, melancholia, or inebriety may favor the production of hysteria, chorea, or neurasthenia in the succeeding generations. This transformation of the neuroses and toxic diatheses in propagation, often results in imbecility. The children of hysterical, epileptic, hypochondriacal, syphilitic, or alcoholic parents are liable to be imbeciles. Phthisical parents also frequently have imbecile children.

Adler says "all these disturbances depend upon an inadequate reproductive power of the nervous system of the ancestors, which is insufficient to provide the association tracts of the descendants with the required nutritive, formative, and functional capacities." In the idiot we may have no mental power at all or feeble-mindedness. Idiocy, according to Ireland, is mental deficiency or extreme stupidity, depending upon malnutrition or disease of the nerve centers, occurring either before birth or before the evolution of the mental faculties in childhood. In idiocy and imbecility are conditions of mental enfeeblement resulting from arrested brain development before birth or in very early childhood. In many individuals the mental faculties never mature, as the brain is incapable of development.

It is difficult to draw the line between the idiot and the imbecile classes. The latter are regarded by some authorities as high-grade idiots. Imbeciles may be well formed and vigorous; they generally exhibit characteristic bodily peculiarities; their cranium is too small, or too large, and liable to varied malformations and asymmetries, the majority of them having an animal-like appearance. As regards mental development they are restricted; they learn to read, write, and count with difficulty, and what they learn, many of them easily forget. At one time I had an imbecile under my care who wrote a fairly good hand. As time passed his writing degenerated into a mere scrawl.

With a very few exceptions imbeciles are vain, unreliable, gluttonous, and prone to be irritable and sulky. Perversion of the genetic sense is the rule; they practise debasing habits, and are often perverted sexually.

*Read at the meeting of the Association of Boards of Trustees, Superintendents and Stewards of the State Hospitals of Ohio, held at Toledo, Ohio, 1903.

Idiots are divided into various classes. We have the absolute idiot, who is incapable of any mental development whatever. Those in a second class present the ordinary symptoms of idiocy, yet may be capable of articulating to a small degree, and of conducting themselves with a fair degree of propriety. They cannot concentrate their minds, however, and it is impossible to educate them. A third class includes those whose attention can be held and who are capable of acquiring a very limited education, and who have some command of language. Those in a still higher class approaching imbecility may be taught to read and write.

The Causes.—Intemperance is a prolific cause of idiocy. Berkley says it is a well-recognized fact that drunkenness at the time of copulation is frequently responsible for the lowest forms of congenital idiocy.

In the majority of neuropathic families when the predisposition is not corrected by marriage, the tendency affecting mental development is downward until idiots appear, the house finally becoming extinct. The intermarriage of blood relations is a subject that has been written upon and discussed for centuries. The opinions of authorities differ on this point materially. It is generally accepted that persons marry who are closely related, any neuropathic tendency present is more likely to be developed in the offspring. Individuals uniting in marriage who have similar nervous diatheses are likely to produce defective offspring.

Profound grief or physical shock acting on the mother produces cerebral defect or generally arrested development in the progeny. "Of ninety-two children born in Paris during the great siege of 1870-1, sixty-four had mental or physical anomalies, and the remaining twenty-eight were weakly. Twenty-one were intellectually defective (imbecile or idiotic), and eight showed moral or emotional insanity. After the great Chicago fire, deformities and mental defects were noticed to exist among the offspring whose mothers were pregnant during and immediately after the conflagration."

The infectious fevers, measles, scarlatina, as well as meningitis of varied bacterial origin, and other morbid processes tend to the formation of cysts and other degenerations of the brain substance with depression and imperfect development of the convolutions.

The cause of microcephalic idiocy may be defective inherited organization, leading to early ossification of the cranial sutures, and necessarily delaying development.

Hereditary syphilis is a factor in the causation of the psychoses of early life. There are twice as many boys as girls born idiots, and 7 or 8 per cent are congenitally blind.

Arterial or febrile diseases may retard mental development. The essential defect of the degenerate depends upon the faulty composition of the substance of the nerve cell, or its ancestor the germ cell; although the character of the defect may be absolutely unknown, we are justified in using the unscientific term, "nervous instability."

To determine the frequency of the association of physical stigmata of degeneracy with abnormal mental states, we examined, sometime ago, one thousand cases in the Columbus State Hospital and recorded the measurements of the head, calculated the cephalic index, and noted abnormalities and asymmetries of the cranium, face, palate and ears. We also noted evidences of defective development of the body and extremities. It was not unusual to find cases with several stigmata present, and among those cases giving evidence

defective mental development, and those showing insanity early in adult life, the presence of numerous stigmata was decidedly frequent. To show this we have taken the records of the first fifty white male patients who were perfectly developed mentally, not trying to find the most unfavorable cases, but simply tabulating them as they came in order.

Measurements of the circumference and crown, and of the occipitofrontal and biparietal diameters of the cranium were made in all cases. By determining the relation of the greatest breadth to the greatest length of the skull, in terms of percentage of the latter, we obtained the cephalic index. In our observations we made allowance for normal variations and recorded only such conditions as were unusual.

The Cephalic Index. Of our fifty cases thirteen had a cephalic index above 80 (*i.e.* the transverse diameter was four-fifths, or 80 per cent., of the occipitofrontal diameter). These have a short index or are shortheaded-brachycephalic. Fourteen were between 78 and 80, sub-brachycephalic. Twenty-three were below 78, long-headed or dolichocephalic. Normal variations range between 74 and 87 according to Berkley. Two of our cases were above 87, hyperbrachycephalic, one 87.9, the other 88.9. Eight were below 74, hypodolichocephalic, 71 being the lowest. The mean cephalic index is considered to be 80.5. Our cases gave an average of 78.3, somewhat below the mean.

The Cranium. This presented nothing unusual in twenty-four cases. Of the other twenty-six, the forehead was low in five, low and narrow in two, low and receding in two, simply receding in one, unusually high in one, broad in one, prominent in one, broad and prominent in one, in all fourteen cases.

In four cases the occiput was small, in four flattened, in one broad and flat, and in two prominent. In one case the occiput was decidedly more prominent on the right side, and in another the occipital protuberance was unusually well marked. M——, whose head gave a cephalic index of 87.7, had a high vertical forehead with a flattened occiput, so that the head was cylindrical.

The hair on the head presented nothing unusual in most cases, but six had very coarse hair, in three of which it was bristly.

The Face. In looking for unusual features of the face, we found none in three cases. Asymmetry was frequently found as follows: the right side was more prominent in three cases; the right eye was on a higher level in four cases, and the left in five; the nose deflected considerably to the right in ten cases, and to the left in five.

The eyes were unusually prominent in two cases and deep set in two. Two cases showed convergent strabismus, one divergent strabismus, and one presented a decided insufficiency of the left internal rectus. The pigment of the iris was so small in amount in one case as to approach a condition of albinism.

The nose was very broad at the base in three cases, thin in one, long in one, and very prominent in five.

The lower jaw was very large in one, and the chin unusually small in two. Two cases had prominent lips.

The Palate. The normal palate varies considerably in height, breadth, and curvature. In our cases we classed palates that were a little higher than normal under the term high or neurotic; when high and somewhat arched, under the term high and narrow, and when extremely narrow, having the shape of a gothic arch, under the term high-arched. The high-arched palate with crowded irregular teeth is so rarely found among normal individuals, and so frequently among defectives that some authorities consider it an index to an imperfect mental development. Our fifty cases do not properly indicate the frequency of such a palate among this class. Ten cases were about normal; twelve had neurotic palates. In thirteen individuals the palate was high and narrow above, in two of which the sides were decidedly asymmetrical. Four presented high-arched palates. The roof of the mouth was flat in three cases, in one of which it was also broad. In three cases it was very broad, and in one it was narrow in front. A median ridge occurred in two cases, and a furrow in two. Longitudinal tori were found twice, and two fossæ in the palate near the median ridge were noticed in one case. Associated with the high and narrow, or neurotic palate, and with the high-arched palate, the teeth were so crowded that in one case they were very irregular, and in another there were two rows in front.

One had an unusually long tongue, one a very short uvula, and two had long uvulas.

The Ear. In the development of the ear it passes from a long smooth-pointed ear into forms resulting from foldings of its edges and walls, so that the normal ear must have certain anatomical parts which we cannot stop to describe here. Arrested development may be manifested in long narrow ears, or in ears that do not have the proper ridges and folds and stand out from the head, or in ears without lobules. The developmental process may have continued too long, and the ears may show an increase of foldings and set too closely to the head.

Man is the only animal that possesses a well-developed lobule to the ear. It is commonly absent in certain African races, and is occasionally found in a rudimentary form in one species of the ape, according to Darwin. Twenty of our cases had lobules of medium size adherent to the skin of the neck on both sides. One was adherent on the right side only. Three showed lobules adherent and much increased in size. One case had small adherent lobules. In twenty-three cases the lobule was normal. In fourteen cases the ears were very prominent, appearing to stand out almost perpendicularly. Three cases presented long ears, three small and one large. In one case the left ear was larger than the right.

The folds of the ears were examined for unusual types. The helix was thin on both ears in eight cases, and one case on the right ear only. It was wide or band-like in two. The fossa of the helix was increased in four cases, and shallow or obliterated in three. The antihelix was flattened in five cases, and increased in prominence in two. The antitragus was prominent in one case, and flattened in another. The concha was broadened and deepened in twelve cases.

The little blunt point projecting from the inwardly folded margin of the ear or helix, found in many ears, was thought by Darwin to be a vestige of the tip of formerly erect ears, because of the frequency of their occurrence, and general correspondence in position with that of the tip of a pointed ear. Of our fifty cases five showed Darwinian tubercles on both ears, three showed them on the right ear, and two on the left. Five ears were perfectly normal.

The Body. This showed nothing unusual in six cases; four were dwarfed, two were excessively fat, and one showed hypertrophy of the breasts. The body hair was absent, or very scant, in fourteen cases, and hypertrichosis was noted in four.

Three had very small external genitals, and three very large. One presented an inguinal hernia of the right side, and another of both sides.

The curvature of the spine was abnormal in many cases, kyphosis in nine, scoliosis in six, kyphoscoliosis in two, lordosis in seven, and lordoscoliosis in two.

The coccyx was prominent in thirteen.

The Extremities. These showed nothing unusual in twenty-four cases. Ten had sharp-pointed shoulders, one had long arms, one very short arms. Seventeen showed syndactylism, in some of which the folds between the fingers and toes were decidedly web-like. This was more often found in the fingers than in the toes. One case had a double little toe on the left foot. Five cases were flat-footed

Counting well-marked cranial peculiarities, stigmata of the ear, facial asymmetry, defects in the palate, the eye muscles, the body and extremities, each under a single head, our notes show that two stigmata were found in seven cases, three in nine cases, four in seventeen cases, five in eight cases, six in six cases, and seven in three cases.

Juvenile criminals in reformatories present a characteristic appearance, due to lack of physical and mental development. They are usually puny and sickly, often deformed, liable to epilepsy, stupid and deficient in vital energies.

There seems to be a tendency to attempt to educate and elevate these unfortunates who are by nature defective and have most of them been born and reared among unhealthy surroundings. Children of drunkards, of criminals, and of degenerates are removed as much as possible from unfavorable surroundings, and the bad effect of vicious habits impressed upon them. The mental development advances along more healthy lines, the individual, through proper education and environment, develops character and will-power sufficient to combat and control evil tendences.

A great many intelligent persons, and some well-read physicians, are inclined to be skeptical in regard to the significance of these signs. In the face of facts such as I have attempted to bring out, and the prominence given to mental and physical stigmata by eminent authors, it seems to me that they are entitled to greater consideration and more careful study. When a degenerate is on trial for his life, or for some crime, the prosecuting attorneys generally try to throw ridicule on the production of these signs as evidence of irresponsibility. They will cite the fact that these stigmata are found in individuals who are noted for special mental brilliancy and so forth.

Those of us who have had experience in the care of mentally deficient people are often astonished at the wit and shrewdness of their remarks. It is a hard question to decide what should be done with the criminal degenerate. It seems to me, if they are mentally deficient, they ought not to be punished with the same severity measured out to a normal individual who commits crime for gain or for revenge, well knowing the enormity of his act. Should they be punished at all? If we can establish the fact that these men are weak and irresponsible, they should not go to the electric chair or to the penitentiary for life. In every State suitable provision should be made for them by the erection of an asylum for the criminal insane. This has already been done in a few States of the Union.*

*I have quoted from Talbot on "Degeneracy" in the Contemporary Science Series, Wm. C. Krause of Buffalo, and others; am also indebted to Dr. Geo. Harding of my medical staff for assistance.

MASTOIDITIS.*

By E. H. POMEROY, M.D.,
HIGHLAND PARK, ILL.

MASTOIDITIS could very properly be discussed under the head of otitis media, it being generally, if not always, an extension of a chronic inflammation of the middle ear to the mastoid cells.

Under the head of etiology, I think it can be safely stated that the disease is always caused by bacterial infection. "Exposure to cold," "exposure to drafts of air," as through a car window, and all other items usually mentioned in the etiology of this disease, are at most no more than secondary or auxiliary causes, and the disease never exists without a bacterial invasion of some form.

The symptomatology of this disease is varied. While there is frequently, probably generally, severe pain accurately localized, yet this is by no means always the case. Probably most physicians of considerable experience in general practice have met with cases which have progressed from an acute attack of otitis media to a very advanced state of mastoiditis without the patient having ever complained of pain excepting the original pain, or earache, accompanying the initial infection, and often there is no history even of that. This has been the case in adults, and probably much more frequently in infants who are unable to localize symptoms, and also in those who have been drugged into insensibility for considerable periods, and where the case has been complicated by enteritis, pneumonia, arthritis, or other manifestations of infection by the same germ which caused the ear or mastoid infection.

The most prominent symptom of mastoiditis, and the one which can be called almost pathognomonic of the disease, is a falling forward and downward or a protrusion, of the external ear. Very frequently there is an appearance of fluctuation behind the ear, which has led the attendant physician to make an incision down to or through the periosteum but without encountering any pus, much to his surprise. Sometimes, however, this treatment has not been disappointing even in the case of genuine mastoiditis, the suppuration finding its way from the mastoid cells through to the surface of the mastoid process beneath the periosteum, and the incision giving a sufficient outlet for the accumulated pus, permanent recovery follows.

I remember, as a medical student, having seen a professor of practice, temporarily conducting a surgical clinic, showing us a patient, probably with mastoiditis, and having a number of us palpate the post-auricular space to feel exactly where the pus was. Most of us being told exactly where to feel the pus could, of course, feel it. The professor of anatomy, happening to be present as a spectator, was also asked to palpate the patient, which he did. When asked if he could feel the fluctuation, he answered in the negative. He was then shown very accurately the point, but insisted there was no pus there. A free incision was made through the periosteum, but without a sign of pus.

Taking a case of a patient at any age, showing a drooping or protruding ear, with or without slight increase of redness of the surface back of the ear, with a history of a preceding otitis media, with or without discharge of pus through the external auricular canal, and the case will almost certainly be one of mastoiditis.

Under the head of treatment comes first the prophylactic treatment, and in no disease is prophylaxis more important than in mastoiditis. The

*Read at a session of the Lake County Medical Society held at Waukegan, Ill., November 2, 1903.

ne point which I wish especially to make is that very case of severe disease in infancy should be refully examined as to the condition of the middle g. The work of Ponfick, as set forth in the *erliner klinische Wochenschrift* of September and ctober, 1897, has demonstrated in a most convinc- g manner the fact that in one hundred autopsies unselected cases of infants dying under the age of o years, there was scarcely one without pus in middle ear. In the overwhelming majority of ese cases this pus had never been liberated. en in three cases, in which death had resulted m unquestionable hereditary syphilis, pus was nd in both ears.

In the *Boston Medical and Surgical Journal* of nuary 18, 1899, I have somewhat elaborately iewed this work of Ponfick's and our application he principles it so forcibly advances in our work Calumet, Mich. Any physician who will take trouble to overcome the difficulty of examining infantile ear can scarcely avoid being convinced he very great importance attached to this sub- The exceptions are so rare that it may safely tated that every infant dying under the age of year has pus, or inflammatory process estab- d, in the middle ear. When it is taken into ideration that paracentesis of the tympanum erly performed will, in the overwhelming ority of cases, give almost immediate relief, trouble and infinitesimal danger of the anæs- ic in these cases will not deter one from giving child the benefit of the operation.

t is almost impossible to read this remarkable k of Ponfick's without being convinced of the ssity of examining most carefully the tym- um in every case of serious disease in infancy, liberation of pus from the middle ear at this e can very properly be called prophylactic tment of mastoiditis.

he further treatment of this disease is surgical. other treatment should be considered as un- ssarily jeopardizing the health and the life he patient. I am perfectly aware that many ents have recovered without intelligent sur- l treatment, but even so, those who have re- ed have run a risk, and have been subjected nnecessary peril by having had the surgical tment withheld. This surgical procedure is simple. A good free incision should be made quarter of an inch posterior to the edge of the rnal auditory meatus, one inch or more in th. Then the periosteum is lifted from about incision, especially forward, and the gouge is d carefully from above downward, or the with the dental engine, all bleeding points g controlled before the bone is opened into. operator should cautiously note the con- on of the bone as depth increases, until the toid cells are reached, then carefully hook and remove the mastoid cells, this curettage king a cavity as large as a small filbert, which y be packed not too tightly with iodoform or er gauze, and allowed gradually to fill with nulation. From the beginning of the surgical cedure to the last dressing, asepsis must be erved in every detail. In the preparation of a ient for operation of this sort I consider lack of gical cleanliness more criminal than if one were paring for laparotomy.

I remember less than ten years ago seeing a sur- on, bearing one of the most honored names in surgical world of England, in the operating rd of one of the most famous hospitals of the rld, preparing to operate in a case of mas- ditis, which had evidently led to a cerebral scess. After explaining to his students the ne- cessity for the utmost care in preparing for an operation of this sort, and demonstrating this by repeated and long-continued scrubbing of his hands, and immersing them for long in alcohol, and then in sublimate solution, and after he was fully prepared, having still some minutes to wait for the patient to be completely anæsthetized, he held his hands carefully away from his operating gown (which I considered wise, as the gown bore evidence of having been in many operations), yet while he was waiting, he very daintily used the nail of one of his beautifully shaped fingers as a toothpick! I did not remain long enough to learn with what particular accident the patient was carried off, or even that he was carried off, but the danger was there.

The treatment other than surgical must, of course, be considered; not only is the physician himself sometimes unprepared for surgical intervention, but also quite frequently either the patient or the parents of the patient may be unwilling to allow surgical procedure until other treatment has failed.

The treatment must, of course, be directed primarily to overcoming the bacterial infection, and the saturation of the system with sulphur seems the best form of disinfection to adopt in the medical treatment of this disease. Laboratory experiments have shown that very small doses of sulphur in the form of calcium sulphide, or the homœopathic preparation called hepar-sulphur, which is a dilution, or powdered attenuation, of sulphuret of potassium in sugar of milk, will as effectually saturate the system as will large doses of sulphur administered by the stomach. Therefore calcium sulphide in doses of one-tenth grain to one-quarter grain, three or four times daily, when the patient is old enough to take a pill; or small doses, one or two grains, of the one per cent. powdered hepar-sulphur every two to four hours in infants is the most advisable form of medication. Ice-bags, poultices, and other external or local applications are of doubtful utility, but may be advisable for the control of pain. Many patients have recovered under this treatment; probably most cases, even of severe mastoiditis, will recover under this treatment, or spontaneously under any treatment or no treatment; but I insist that the peril is so constant and so great with this bacterial invasion of the mastoid cells so close to the brain, in the presence of the known history of many deplorable fatalities, we are not justified in withholding surgical procedure in any case of mastoiditis in which surgical procedure is feasible.

REMARKS ON THE PREPARATION OF VACCINE VIRUS.*

By JOHN F. ANDERSON, M.D.,

PASSED ASSISTANT SURGEON AND ASSISTANT DIRECTOR HYGIENIC LABORATORY, UNITED STATES PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

In a paper read before the New York Academy of Medicine in February, 1902, Dr. M. J. Rosenau, Director of the Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service, called attention to the fact that much of the vaccine then on the market showed a high degree of microbial contamination. He attributed this to the fact that many of the manufacturers, on account of the great demand for vaccine, were placing their product upon the market "green" or too soon after collection from the calves, and before the glycerin had exerted its full germicidal action.

In a more complete study, the results of which

*Read at the thirty-first annual meeting of the American Public Health Association, held at Washington, D. C.

were published as Bulletin No. 12 of the Hygienic Laboratory, he emphasized this point and showed that too much dependence had been placed by manufacturers on the germicidal action of the glycerin.

The germicidal action of glycerin is feeble. It probably acts by virtue of its great affinity for water, which it abstracts from the germ. Its germicidal action is much greater at the temperature of the body than in the ice-chest. Pus cocci are killed by it in the incubator in two weeks, but live for months in the ice-chest. Rosenau states that it asserts its greatest germicidal action in the first twenty-four hours, that the bacteria of the colon group are markedly resistant to its action, and that it has practically no effect upon spores.

Copeman, in 1891, originated the idea of preserving vaccine pulp with glycerin. He claimed that it not only exerted an antiseptic action on the bacteria found in bovine virus, but that it gradually destroyed those contained therein.

The Act of Congress approved July 1, 1902, entitled "An act to regulate the sale of viruses, serums, toxins, and analogous products in the District of Columbia, to regulate interstate traffic in said articles, and for other purposes," and regulations approved in accordance with said act, imposed upon the Public Health and Marine-Hospital Service the inspection of establishments manufacturing vaccine, serums, etc. Commissioned medical officers not below the grade of Passed Assistant Surgeon are to make the inspections."

The recent inspection of establishments was made by two officers detailed for that purpose by the Secretary of the Treasury. The inspectors were received with courtesy by all of the manufacturers, and every facility given them for as thorough an inspection of their plants as possible. Some of the plants were found to be conducted most excellently; stables and barns constructed according to the highest sanitary requirements, care and feeding of the vaccinated calves all that could be asked; methods of collecting and preparing the virus conducted with as great attention to prevent accidental contamination as is possible in the handling of such a substance as vaccine virus.

I am sorry to say that some establishments were not so conducted. I think I may, with benefit to all, give, in a few words, some of the most notable faults that were found. The barns where vaccinated calves were kept were, in some cases, simply a portion of the building partitioned off, horses in some instances being kept in the other part of the building, either for the production of antitoxin or for general use. The close proximity of horses was an added source of danger of tetanus contamination. The floors often were of wood, soaked with the discharges from the animals and not properly sloped and guttered. Although summer, the windows were not screened in some instances. When the pulp was to be taken the site was flooded with ordinary tap water, and then the pulp was scraped off with a curette and put into an unsterilized container. The pulp was weighed, mixed with the proportion of glycerin used by the manufacturer, ground, and then placed in the ice-chest until it was desired to be put in the tubes or on the points for marketing. The methods of sterilization of the points, tubes, and other containers were often crude.

Laboratory examination of virus from such plants showed a high degree of bacterial contamination, the most common organisms found being *Staphylococcus pyogenes aureus*, *albus* and *citreus*, *Staphylococcus cereus*, *albus* and *flavus*, *Staphylococcus epidermidis albus*, *Proteus vulgaris*, *Bacillus subtilis*, yeasts and molds, and not infrequently streptococci. Some of the organisms were found virulent for laboratory animals. Tetanus was never found, although searched for most carefully. As high as 74,000 bacteria per vaccine tube were found in one lot examined.

The faults found in certain of the places showed the great need of some control of these products. I take pleasure in saying that when faults in construction and administration were discovered, the manufacturers showed a ready appreciation and willingness to remedy the same. Some establishments which at the first inspection were reported against, having remedied the faults found, have been reinspected and granted licenses.

Recently some valuable work has been done with other substances than glycerin to be used in the destruction of the bacteria found in vaccine. These substances are sodium biborate, boracic acid, carbolic acid, chloroform, and potassium cyanide. Of these chloroform seems the most valuable. Allan B. Greene, in a report to the Local Government Board of England, says that by the use of chloroform vapor the crude pulp is freed from non-spore bearing germs in from a few hours to seven days, while the active agent of the vaccine remains potent as long as in the glycerin control and in six cases longer. The quick elimination of the extraneous bacteria by this method is a great saving in time as compared with the use of glycerin which rarely exerts its full effect before the fourth week. Chloroform, being extremely volatile, can be allowed to evaporate from the vaccine under aseptic precautions after being allowed to act as long as desired. It would be especially useful in hot countries where the active agent in vaccine does not retain its potency long, or when, as in epidemics, sudden calls are made for large quantities of vaccine virus.

Gaylord and Wheeler, in a recent article, have called attention to the use of a solution of potassium cyanide for the destruction of bacteria in vaccine. They state that a $\frac{N}{100}$ solution exerts a complete bactericidal action upon vaccine without affecting the potency of the virus, and that while it is an active poison it is so volatile that in five or six days no trace can be found in solutions kept in test tubes simply plugged with cotton.

CHANNELS OF INFECTION OF TYPHOID FEVER.

The channels of infection of typhoid fever are far more numerous than was at one time believed to be the case. Putting on one side direct infection, water was deemed, but a comparatively few years ago, to be almost the only mode by which the disease was transmitted. It was later discovered that milk not infrequently played a more or less important rôle in the transmission of typhoid fever. For some time water and milk were regarded as the sole agents in the conveyance of the typhoid bacillus to human beings. However, of late years a change has come over the attitude of bacteriologists and physicians with regard to this matter, and several epidemics of typhoid fever have been traced to causes in which neither water nor milk was a factor.

Dr. Anders, in his recent textbook of the "Practice of Medicine," states that in his opinion, in the vast majority of instances, the poison is transmitted from those affected with the disease to those in good health through the drinking-water supply. The poison is frequently conveyed by infected milk. Solid forms of food (salads, celery, fruit) may be contaminated by infected water or dust or by the fingers of the nurse or patient. During the late Spanish-American war, and to a far greater extent in the more recent Boer war, the typhoid bacilli were carried from the latrines directly to the victims, or to the kitchens and mess-tables by swarms of flies. Vaughan, after careful investigation, confirmed this view. Oysters, on many occasions, have been proved to convey the infection, the testimony to this effect is so overwhelming that there can be no doubt as to its accuracy. Newsholme, indeed, writing in the *British Medical Journal*, June 8, 1895, attributed one-third of a total of fifty-six cases of typhoid fever to the eating of raw shell-fish. Tooth has directed attention to the importance of sand-storms as a means of contaminating articles of food with the bacillus. Food from animals affected with fever has been put down by some as a mode of transmission. Fodor found that the mortality from typhoid fever in Buda-Pesth was greater in those houses which were supplied by well water than in those supplied by pipe water (filtered); and greater in those houses where the ground water was more impure, and where the ground was more polluted.

The British Review of Reviews, January, states that an outbreak of typhoid fever in the metropolitan borough of Hackney has been traced by the Medical Officer of Health, Dr. J. King Warry, to watercress. All ordinary sources of typhoid fever, such as water, milk, and sanitary defects, were excluded. But 55 per cent. of the patients had eaten watercress in the three weeks before illness. Seventeen samples of watercress obtained from dealers who supplied the patients were examined bacteriologically and found to be polluted with organisms of the colon-bacillus type, and the water of one of the watercress beds situated in the metropolitan district of West Ham contained fifty colon bacilli per c.c. These beds, which seemed to be the chief source of the outbreak, were found to be fed by almost undiluted sewage from the badly polluted river Lea.

Dr. George Newman writes in the January number of the *Practitioner* concerning the channels of typhoid infection in London. The writer suggests that in London, water is by no means the commonest channel of typhoid infection, and further intimates that amongst a wonderful variety of suggested means of infection two emerge, and year by year occupy a more prominent place in the records. The first is infection by contact with the persons or belongings of previous cases, and the second is infection by the conveyance in food, particularly shell-fish. Dr. Newman points out that the view usually held by writers on general medicine seems to be that this mode of conveyance is exceptional, and therefore he furnishes evidence in support of the view that it is not infrequently the cause of spread of the disease. By this it is not meant that typhoid fever is directly infectious in the same degree as, say, scarlet fever, but rather that it is indirectly spread by means of infective excreta to healthy persons coming in the way of personal infection. Numerous instances are given of such occurrences.

With regard to infection through contaminated shell-fish, etc., the writer says: "It has been known since 1894 that oysters and other shell-fish may convey the infection of typhoid fever. We have not space here to enter into a discussion on the scientific evidence of that fact, but it may now be generally accepted as proved. Turning to the metropolis, we find that it was in 1894 that there seemed to be in London districts increasing evidence of a relationship existing between the consumption of shell-fish and enteric fever. It was not, however, of a reliable character, and Mr. Shirley F. Murphy, the medical officer for the administrative county of London, wrote as follows in his report for 1894: "The evidence which is supplied by the results of the inquiries made by metropolitan medical officers of health does not do more than establish the fact that antecedent to the occurrence of typhoid fever certain of the sufferers, and not in most cases a large percentage, had eaten oysters. There is no proof that the oysters in question had received infective contamination, nor is their source traced out except in a few cases. Further, there is no information as to the proportion of persons in the general population who had consumed similar oysters or shell-fish of any kind." In 1895 further cases occurred apparently traceable to shell-fish. In 1896 Dr. Timbrell Bulstrode's report appeared, and this naturally stimulated inquiry, which resulted in the following years (1897–1900)

revealing a large number of cases apparently due to this cause. They all tell the same story, and therefore it will not be necessary to furnish an extensive list of cases. During 1901 and 1902 the autumnal rise of enteric fever in London was not marked, but increasing evidence was forthcoming as to the channel of infection in the cases which were notified." The returns for 1902 are then given showing that a large proportion of typhoid-fever cases were due to the eating of infected shell-fish. A similar result was noticed in Wandsworth. In fact, from all parts of the metropolis evidence was freely available that a large number of cases of typhoid fever were directly traced to the consumption of contaminated shell-fish.

Cases of enteric fever have also occurred in different metropolitan districts in which it would appear that there is evidence leading to the idea that even fried fish may convey enteric infection. The conclusions drawn by Dr. Newman are as follows: "If it be true, as would appear, that the case rate for typhoid fever in London remains fairly constant year by year, and at the same time water-borne infection is not the chief channel, it seems reasonable to conclude from the above facts that personal contact and polluted food (especially shell-fish) are the main channels of infection. In any event, a case seems to be made out for further inquiry on these two lines in any investigation into this disease, and for a study of the direction which preventive measures should take."

DIPHTHERIA IN THE UNITED STATES NAVY.

THE readers of the MEDICAL RECORD will doubtless be interested because of the astonishing features presented in the account of an epidemic of diphtheria which occurred not long since in the United States Navy. The *Buffalo*, with nearly 1,000 persons on board, arrived at New York in October, 1902. Without being disinfected she proceeded to the Norfolk Navy Yard on October 22, and there received on board 450 landsmen for training. These, with her regular crew, made a total ship's company of about 750. With these persons on board she remained forty-four days at the Norfolk Navy Yard undergoing repairs. During these days thirty-eight cases of epidemic catarrh were treated. On December 4 she left Norfolk and arrived at New York on December 7, sailing thence for the West Indies on December 12. Five cases of sore throat developed before leaving Norfolk, and ten others before sailing from New York. Other cases appeared, some of them with severe general and local symptoms, swelling of cervical lymphatics, etc. On December 22 the ship sailed from Samana Bay for Kingston, Jamaica, and on the same day two cases appeared which were malignant in character. Upon arrival at Kingston on December 25, anti-diphtheritic serum was obtained and administered to both of these cases, but without avail, one dying on the 25th and the other on the 26th. The ship sailed at once for Pensacola, where she arrived on December 30. Up to this time forty-two cases of so-called tonsillitis and eight of diphtheria had been admitted to the sick list. Forty-eight cases were transferred to the Naval Hospital at Pensacola, where bacteriological examination revealed the true nature of the disease, and an abundant supply of anti-diphtheritic serum was obtained. The ship was also disinfected as thoroughly as possible without vacating the vessel. New cases of diphtheria, however, continued to appear, and the accommodations at Pensacola proving inadequate, the ship was ordered to Port Royal, S. C., where she arrived on January 17. On January 22 the vessel was vacated, and thoroughly disinfected, the crew being quartered on shore. On January 28 the hospital was filled to its utmost capacity, and new cases were still appearing at the rate of four or five a day. On February 1 206 men of the crew proper were returned to the ship, the 400 landsmen being left on shore. Owing to the crowded conditions of the hospital a portion of the sick were kept for a time in the barracks in the same room with the well—a canvas screen alone separating them. At length adequate accommodations were provided, and the sick were properly separated from the well. On February 17 the services of a bacteriologist were obtained, and on February 28 the bacteriological examination of the throats of all the well was begun. All those who showed the presence of diphtheria bacilli, and were thus a source of danger, were isolated. On March 25 the *Buffalo* sailed for New York, with all well on board. Twelve landsmen with diphtheria bacilli in their throats, and thirteen convalescents were left behind for further treatment. The total number of cases was 137, the number of deaths being two. The above history is gathered from an article by George E. H. Harmon, M.D., in the *Journal of the Association of Military Surgeons*, February, 1904.

The salient points, with respect to this epidemic, are as follows: The first cases (five) of sore throat developed previous to December 4. Ten others appeared before December 12, when the vessel left New York. The thought that the disease might be diphtheria was evidently, however, not entertained until December 22, when two malignant cases occurred which were speedily fatal. Upon arrival at Pensacola, fifty cases had developed. It must then have been evident, since the nature of the disease was there established by bacteriological examination, that the infection of diphtheria was well disseminated throughout the ship's company. Nevertheless, no attempt, based upon bacteriological examination of the throats of the well, was made to separate those who were a source of danger from the others. This was not undertaken until nearly two months later, on February 28, when eighty-seven more cases had developed. Then the carrying out of isolation on an intelligent basis in a short time put a stop to the development of further cases.

It is, indeed, strange that in a civilized and enlightened nation such an epidemic as this should have been a possibility. That it could have been prevented with the greatest ease is an absolute certainty. The statics of the first five cases which developed before leaving Norfolk on December 7 should, of course, have been determined. The proper isolation of these and also those who were well but showed the presence of diphtheria bacilli in their throats, combined with the extended prophylactic use of antidiphtheritic serum and, furthermore, with subsequent efficient disinfection of the vessel, would certainly at once have put a stop to the spread of the disease. As it was, no sort of sufficient means were adopted until February 28, nearly three months after the appearance of the first cases.

The prophylactic use of antidiphtheritic serum, a well-recognized and established preventive, was not undertaken at all, except in the cases of a few hospital attendants. It is a wonder that the number of cases were not double those which actually occurred.

The MEDICAL RECORD has no word of censure for those under whose guidance the epidemic here described was allowed to progress, but in all kindness it would deplore the conditions which make such an occurrence possible. Those who are qualified to speak upon these matters know that of all the so-called contagious diseases, with the possible exception of smallpox, diphtheria is the most easily preventable when it appears under conditions in which those who have been exposed can be controlled—such as in institutions of various kinds, aboard ships, etc. The measures which will bring about this result, are: (1) Isolation of all who show diphtheria bacilli in their throats. (2) The extended prophylactic use of antidiphtheritic serum. (3) Efficient disinfection. By utilizing these means an epidemic of diphtheria, occurring under the above conditions, can be checked every time. To those outside the Navy Medical Service, the consideration of this epidemic is full of instruction, as showing the consequences which resulted from a lack of the utilization of means, the efficiency of which is sure.

ANNUAL REPORT OF THE NEW YORK STATE CHARITIES AID ASSOCIATION.

The thirty-first annual report of this association has just been issued. Among other items of interest contained in this report, is the report of the joint committee on the care of motherless infants, which states in part that, although many of the babies under the care of the committee have been subjected to neglect and exposure at a very tender age before being received by the committee, the number of deaths among them is very small. The mortality rate for the past two years has been actually lower, according to the statistics of the Board of Health, than the mortality rate among all children under two years of age in the city of New York, which was for the year 1900, 13 per per cent.; for the year 1901, 12 per cent.; and for the year 1902, 11.8 per cent. The committee's report goes on to say: "When it is remembered that practically all the foundlings, when they were received at the Infants' Hospital on Randall's Island, died before reaching the age of two years, it is most gratifying that the life-saving value of the work of the committee should be so great."

The committee not only receives foundlings, but abandoned babies and infants who have fallen to the care of the city because their relatives are unable to care for them. The committee now takes all the Protestant foundlings and abandoned babies, and a large proportion of the other motherless babies who are Protestants, from the Boroughs of Manhattan, the Bronx, Brooklyn, and Queens. According to a long-established rule, foundlings and other babies, of whose parentage nothing is known, are baptized alternately Protestant and Catholic, and the Catholic children are taken in charge by the Guild of the Infant Saviour, while the committee cares for the Protestants. The last mentioned babies are all boarded in carefully selected houses, each with a different family, and most of them with women who have lost their own babies, and act as wet nurses to those in charge of the committee. When old enough these babies are handed over to the New York State Charities Aid Association, and transferred to the care of the Placing-out Agency of that society.

The report of the New York County Visiting Committee for the year ending September 30, 1903, is, on the whole, satisfactory. It is stated in the report that "In the Department of Public Charities, building after building has been renovated, brought as nearly up to modern standards as circumstances permitted, and a score of new buildings have been started, and pressed toward completion under adverse conditions arising from strikes, and from limitations in the authorized methods of contracting."

The Board of Trustees of Bellevue Hospital has been granted an appropriation for plans, and has been enabled thereby to retain thoroughly competent architects, whose plans, now far advanced, show a well-ordered group of buildings which will place the new Bellevue Hospital, in architectural design, equipment, and adaptation for hospital service, in the front rank of the general hospitals in this country. Gouverneur Hospital is to be completed under plans made possible by a generous appropriation.

Work on the new Harlem Hospital will be commenced in a few weeks upon a site at One hundred and Thirty-sixth street and Lenox avenue.

A new site for Fordham Hospital has been secured on St. John's College grounds, adjacent to Bronx Park, where will be erected a modern hospital, with over two hundred beds, a nurses' home, and stable and morgue.

The report of the Visiting Committee to the Craig Colony finds, as last year, ample cause for censure in the management of that institution. The following specific recommendations are made: "First, That for the filthy patient, the ordinary hair mattress, constantly soiled in spite of greatest care, be replaced with a bedding very satisfactorily employed in Germany—a crib, partly filled with a so-called 'wood wool,' in which the patient lies. It is economical, comfortable, absorbent, and sanitary, since it can be readily burned when soiled.

Second, Some method of mental or physical drill, or games should be introduced, by which many patients could occupy at least some part of each hopeless day. The gain already secured in table manners for these unfortunates by tact and patience, as well as the brilliant results achieved by Bourneville at the famous Bicêtre near Paris, should certainly stimulate serious effort in this direction.

A generous equipment of the scientific department, in the opinion of the committee, is very essential. Only thorough study of the clinical and pathological conditions underlying epilepsy can ever clear up a subject of which so little is known. The committee, therefore, think that no expense should be spared in fitting up the laboratory recently completed.

The report of the New York State Charities Aid Association is far too voluminous to be dealt with within the limits of an editorial, but the public may rest assured that the work of the association is carried out with energy and intelligence, and that the outcome is to the benefit of all concerned.

Prevalence of Diphtheria.—There is said to be an epidemic of diphtheria at Lake City, Ill. All infected houses have been quarantined, public schools have been closed, and public gatherings prohibited.

Cremation.

In the *Hospital*, January 30, is a review of the progress made in cremation in Great Britain. *Public Health Engineering*, June 27, 1903, is largely quoted from. The history of the origin and development of cremation in Great Britain is highly interesting. Like most measures of reform in that country, the advance of cremation has not been rapid. The motto of the British appears ever to be "*festina lente*," and cremation has undergone its period of probation before being accepted by the masses. However, now the movement is a forward one, and bids fair to gain ground. Still more quickly in the future.

The first crematorium in England was opened by the Cremation Society of England at Woking, in 1885, and the number of bodies cremated annually increased continuously up to 1900, during which year 301 operations took place, the total up to the end of 1902 being 2,119. In 1892 a crematorium was opened near Manchester, followed by one in Glasgow in 1895, and by one in Liverpool in 1896. So far these crematoria had been started by private companies, but under the provision of certain acts, the corporations of Hull and Darlington opened crematoria in 1901, and under similar powers the corporation of Leicester also completed a suitable establishment in 1902. In addition to the crematorium at Golder's Green, near London, the City Corporation of London have also taken up the subject, and the construction of a crematorium at the City of London Cemetery at Ilford is about to be commenced. The number of cremations carried out at these establishments during the past ten years has slowly but steadily increased, being 131 in 1893, and 446 in 1902.

In the United States there are twenty-five establishments, at which about 2,700 cremations per annum take place; in Italy there are twenty-seven crematoria, seven in Germany, two in France, three in Switzerland, two in Sweden, and one in Denmark. The British Parliament passed the Cremation Act, which authorizes any burial board, council, or other local authority having powers and duties of the burial board, and any local authority maintaining a cemetery, to provide a crematorium to be used under regulations made by the Secretary of State.

The committee appointed to draw up these regulations made special inquiry into the question of cremation being used to destroy evidence of crime, and in the report admitted that while no regulations could be formed which would entirely eliminate the risk, yet they concluded that regulations could be framed which would so far reduce the risk as to make cremation at least safe as the existing method of burial, as in certain circumstances the law even now permits burial without certification of the cause of death. Two great advantages over earth burial are: (1) Greater safeguarding of the health of the living, and (2) the absolute destruction of the germs of contagious diseases, which is rendered perfectly certain where the human remains are destroyed at a temperature of 1,800 to 2,000° Fahrenheit, now attained in cremation furnaces. The resuscitation of diseases by disturbance of the ground in which many years before diseased bodies had been buried, has been proved over and over again, and even without intentional disturbance of such ground there is always the possibility of germs being brought to the surface and dispersed in the air by natural action such as that of earth worms.

The verdict brought in by the majority of those competent to pass an authoritative opinion on the subject of cremation, is that, for sanitary reasons alone, the process should be adopted in the vicinity of large cities. Sentiment has been the cause of prejudice against cremation. The fear that death by poisoning might escape detection if cremation were to become general, is not justified to the extent which is popularly believed. The arguments in short, in favor of cremation outweigh those against the process.

Concerning Doctors.

Mrs. Earle gives, in the *British National Review* for February, her opinion of doctors. The writer is not by any means enamored of the medical profession, and seizes the opportunity to pay its members several left-handed compliments. Mrs. Earle however, is a great admirer of Dr. Alexander Haig and of his doctrine that we should avoid all uric acid and xanthin-containing foods, which he considers harmful, such as meat, fowl, fish, tea, coffee, cocoa, pulses, asparagus, and some other vegetables, and refrain from all alterative and purgative drugs. The writer declares that poor people in Great Britain have lost the art of feeding children. What, she asks, should be our mental attitude toward doctors, and answers by saying that we should learn from them all we can, and should help them as much as possible by perfect openness and truthfulness, and should let them benefit by our experience and common sense, and should let them know that our object is to attain a better state of general health, and not to make a sudden and rapid cure by means of medicines which only cause momentary alleviations. Mrs. Earle finds that both doctors and the public are somewhat scornful at the highfaluting moral attitude assumed by food-reformers, teetotalers, and abstainers of all kinds, and she owns to having, at one time, sympathized considerably with this point of view. She considers, however, that the knowledge one picks up in the course of life are contingent upon obedience to the whole law, physical as well as moral, and that moral obedience will not atone for physical sin and *vice-versa*.

The Etiology of Carcinoma.

Fresh views as to the cause of the different forms of cancer are continually being advanced. Investigators in all parts of the civilized world are earnestly engaged in the endeavor to trace the disease to its fountain head, and in truth it must be said that a certain amount of definite progress has been made in this direction. British scientists have been especially active during recent years in this line of research and have contributed valuable additions to the sum total of our limited knowledge of the etiology of cancer.

Mr. Keith W. Monsarrat, in the *British Medical Journal*, January 23, has an article on the subject. In 1899 he described the morphological characters of an organism isolated from carcinomata. During the four years which have elapsed since that time he has continued these researches, and now reports their result with regard to the morphological characters associated with the clinical type of carcinoma—that affecting the female breast. The writer claims to have isolated an organism which will grow on nutrient media, has constructed a scheme of its life history, in which two cycles were traced—the one a vegetable budding cycle, the other a sporulating cycle, and which when injected into living animals will produce a new growth in their tissues. He has further come to the following conclusions: The organism initiates in endothelium and epithelium a process of proliferation, as a result

of which masses of new-formed tissue are built up which consist of a parenchyma and a stroma, and grow and extend actively from their centers of origin. This new cell-mass formation may be associated with growth of a similar character in neighboring glands, and some evidence was also provided that visceral metastasis occurs. Intracellular bodies are demonstrable in carcinomata mammæ, which present the same features as the intracellular parasites of the experimentally produced nodules. "The evidence derived from these researches, says the writer, "points to the conclusion that the organism described is an etiological factor in the morbid process known as carcinoma mammæ." Without taking so sanguine a view of the result of the researches of Mr. Monsarrat, as he himself does, there would seem to be some good grounds for the belief that he has unravelled a little of the tangled skein which enfolds the origin of cancer. The unremitting and painstaking labors of those who have devoted themselves to cancer research cannot but in the long run bring forth splendid results, the long-desired goal may even be reached.

An Extraordinary Case of Prolonged Sleep.

In the records of prolonged sleep it is doubtful if there is a case more remarkable than that recorded by Dr. E. Herbst, a dentist of Bremen, in the *Berliner klinische Wochenschrift* for February 1, 1904. This occurred in a woman, forty-four years old, living at Grambke, a town near Bremen, who, according to the account, had slept for seventeen years. She had been entirely well for a period of 12 years previously, although prior to this she had on one occasion slept for thirty weeks. For a brief time before her long sleep she had complained of a peculiar headache and that she was unable to retain anything and to read. She suffered frequently from a sense of great fatigue and often slept for from twelve to twenty-four hours. Throughout the long period of sleep the ingestion of food was not interfered with, and the woman ate and drank when the rest of the family ate and drank, although her food had to be cut up and macerated. For the purpose of eating she was placed upright and supported by means of a hand upon the back. When thirsty, she smacked her lips until given drink, and she became restless when food was not supplied at regular intervals. She frequently took cold, on one occasion had influenza, vomited food that she could not digest, at the same time sweating profusely, and was thus not immune from everyday ills. When she desired to void the rectum or the bladder she indicated her wish by moaning. The eyes remained closed, motility was unimpaired, she threw herself about in bed and moved all of her members—in a word she behaved like a person sleeping normally. On awaking she had a feeling as if she had slept but a single night, calling to a sister that it was time to arise and manifesting surprise that a brother who had seventeen years previously when a soldier wore no uniform. To her father she stated that her head was now clear. Her memory was unobscured, so that she was able to recall every detail of her experience seventeen years previously as if it had occurred but yesterday. The eyes appeared to have become somewhat myopic, although she recognized everything before her. She had increased in weight and presented the appearance of a woman of her years. The parietal bones, however, were exceedingly prominent, so that the skull had a peculiar spherical shape. In reply to the inquiry as to whether she had dreamed she answered in the negative. Her conduct was that of a person seventeen years younger. Speech was at first difficult, perhaps in consequence of loss of the teeth, most of which had fallen out. Motility was preserved, although walking was difficult, though improving rapidly. The woman awoke from her long sleep at the time of a fire in the neighborhood of her home, with the ringing of bells. The relatives were not inclined to believe that these circumstances had anything to do with the waking, as the bells had often rung before and violent thunderstorms, of which as a child she had been afraid, had been without effect.

This record is almost too startling for comment, and we doubt if its equal can be found in the literature. From the context it cannot be determined whether the individual was constantly under professional observation or not, but the communication appears in such a sober and reputable journal that its authenticity cannot be questioned. A decision as to whether the condition was one of true sleep or not will depend upon the individual definition of that term. At this distance the record of the case reads like that of one of hysterical narcolepsy of unusual duration.

News of the Week.

Dr. William Kelly Simpson has been appointed professor of clinical laryngology at the College of Physicians and Surgeons, New York (Medical Department of Columbia University), to succeed Prof. George M. Lefferts, resigned.

Typhoid Fever in Philadelphia.—Dr. A. C. Abbott, President of the Philadelphia Bureau of Health, predicts an epidemic of typhoid fever in that city. Sixty new cases of the disease were reported on February 28 and 29. Dr. Abbott believes that with the advent of warmer weather the earth will be loosened and the accumulated dirt and filth of the winter washed into the river by the rains and pumped into the water-mains. The preventive is to boil thoroughly all water used for drinking and for domestic purposes generally.

Filtration of the Columbus Water Supply.—An ordinance was passed this week by the Council of Columbus, Ohio, providing for the submission to the voters at the next general election of a proposition to issue $1,500,000 bonds for a filtration and softening plant for the City Water Works. The measure was inspired by the fact that there have been to date this winter 1,522 cases of typhoid fever.

Increase in the Death Rate.—The report of the Board of Health for the week ended last Saturday shows a death rate of 23.35, against a rate of 21.84 for the corresponding week last year. During the week there were 328 deaths from pneumonia, 59 from bronchitis, 126 from bronchopneumonia, and 24 from influenza.

The Spitting Nuisance.—Health Commissioner Darlington of New York City has caused public announcement to be made that no further leniency is to be shown toward violators of the provision of the Sanitary Code that makes spitting in public a misdemeanor. Officers of the Health Squad have been ordered to make summary arrests in all cases. The abominable habit of voiding the nasal secretions by blowing the nose on the sidewalk without the use of a handkerchief is rapidly growing as must be evident to anyone with habits of observation. Whether or not that shares with spitting in the prohibition we do not know, but if not it should be specifically included, for a more

disgusting and hygienically wicked practice does not exist.

Bureau of Information for Students in Paris.—A correspondent of the *New York Times* writes concerning a new department opened on February 15 at the Sorbonne. The movement, which is due to the initiative of Dr. Blondel, consists of the installation of a Bureau of General and Scientific Information, bringing within reach of every visitor or student a mass of information hardly to be acquired in any other way. The bureau is administered by a staff of employees speaking several languages, and undertakes to bring any student or visitor into touch with persons or institutions, societies, laboratories, lecturers, or authorities on any subject which he may wish to examine. Addresses of embassies, Consulates, compatriots in the capital, may all be obtained at the bureau in the Sorbonne, together with particulars of lectures, courses of instruction in law, medicine, hygiene, engineering, the fine arts, literature, or sciences of the most abstruse description.

A Diploma in Tropical Medicine.—The University of Cambridge has recently announced that it will grant to applicants who have fulfilled the stipulated conditions regarding time of study, and who pass successfully an examination, a diploma testifying to knowledge and skill in tropical medicine and hygiene. The examination will have reference to the nature, incidence, prevention, and treatment of the epidemic and other diseases prevalent in tropical countries. It will comprise the following subjects: (1) The methods of pathological and bacteriological investigation. The examination of the blood. The characters, diagnosis, and life-history of animal and vegetable parasites. The examination, chemical and microscopic, of poisoning or contaminated foods and waters. (2) The origin, pathology, propagation, distribution, prevention, symptoms, diagnosis, and treatment of the epidemic, endemic, and other diseases of tropical climates, including malaria, blackwater fever, trypanosomiasis, relapsing fever, dengue, yellow fever, plague, tetanus, beriberi, dysentery and hepatic abscess, cholera, enteric fever, Malta fever, and specific diarrhœal affections of the tropics, diseases due to cestode and other worms, filariasis, bilharzial disease, specific boils, sores, and other cutaneous affections, mycetoma, ophthalmic affections of the tropics, affections caused by poison-cut plants and animals, and by poisoned weapons and sunstroke. (3) The general effects on health in the tropics of seasons and climate, soil, water, and food. Personal hygiene, acclimatization. Principles of general hygiene, with special reference to food and water supplies, sites, dwellings, drainage, and the disposal of refuse. The sanitation of native quarters, camps, plantations, factories, hospitals, asylums, jails, pilgrim and coolie ships. Principles and methods of disinfection. The examination will be partly in writing, partly oral, and partly practical and clinical. The clinical part will be conducted at a hospital for tropical diseases, at which cases will be submitted for diagnosis and comment. The applicant must be a legally qualified British practitioner, and must pay an examination fee of six guineas. The examination for 1904 will be held on August 9, and the two following days.

Consumption Declared Contagious.—The Nebraska State Board of Health promulgated on March 1 a rule requiring physicians to report promptly, for purposes of quarantine when deemed necessary, all cases of consumption. Any physician, householder, or landlord who fails to comply is subje to a $100 fine. Consumption is thus formally i cluded in the list of contagious diseases.

Ankylostomiasis in Porto Rico.—The Legislat of Porto Rico has appropriated $5,000 for the penses of an investigation into the prevalence anæmia in the island. Captain Ashford of t military hospital has been appointed to cond it.

Measles in a University.—An epidemic of mea has broken out among the students of the U versity of Wisconsin, and one hundred are confi to their rooms. The malady first made its pearance two weeks ago, but it was not unti week ago that it began to spread. The contag is believed to have been introduced by a stud who attended the junior promenade while in early stages of the disease.

Dr. Mary A. Dixon Jones of this city has cently been elected a member of the British Gy cological Society of London. This is a well-deser honor, accorded in recognition of the excellent w by Dr. Jones in the field of tumors of the uterus its adnexa.

The Supply of Trained Nurses in Cincinnati is equal to the demand. Although there are over graduate nurses practising in the city, owing the unusual amount of sickness, many families compelled to do without their services.

Additions to the Medical Staff of Cook Co Institutions.—Hereafter the consulting staff of Cook County Institutions at Dunning, Ill., be composed of one specialist each in internal m cine, tuberculosis, insanity, pathology, and surg

Suture of the Heart.—Dr. Francis T. Stew on February 29, successfully introduced six sut through the wall of the left ventricle of the h in the case of a colored man admitted to Jeffe Medical College Hospital with a stab wound of left side, and signs of injury to the heart.

Dr. Joseph Brown Cooke has been appoi Adjunct Professor of Obstetrics in the New Y Polyclinic.

Increase in the Price of Camphor.—The pric gum camphor, for supplies of which the w depends upon Japan, has risen steadily since first rumors of war. Last October, the whole price of camphor was about fifty-eight cents a po in bulk. The last shipment from Japan wa December, and since then prices have gone up nearly a dollar a pound in bulk at wholesale. is said that America has but four months' sup Although the price of camphor may advance e further, there will probably be no famine, s the large plants recently established to manufac camphor artificially will be able to supply the h demand.

Dr. P. S. Connor, Jr., has been appointe district physician of Cincinnati, Ohio, to rep Dr. Harry Thomas resigned.

Reports of Cincinnati Hospitals.—Reports mitted to the Board of Medical Directors of cinnati Hospital show that in the past year 13, persons applied for treatment; of these 6,423 sons were admitted. Total number of operati was 396. Poison cases to the number of seve were treated, of which thirteen proved fatal. fifteenth annual report of St. Francis Hospi Cincinnati, shows that during the last year 1, patients have received treatment.

Dr. S. D. Clayton has been chosen Medical aminer in the Pension Office Board in Cincin to fill the vacancy left by the death of Dr. Spen

The Examination of Medical Officers for the ional Guard of Illinois has been postponed until ril 30. All those who desire to take this exination should apply to the Surgeon-General, . Nicholas Senn. The examinations will be d at Rush Medical College, beginning at 9 A.M.

ift to Augustana Hospital.—The sum of $20,000 l be given to the Augustana Hospital of Chicago, ording to the will of the late Thomas D. Lowther.

he police of Chicago also are beginning to enee the ordinance drawn by the City Council hibiting spitting on the floors of public conances or public buildings. Several men have n brought into court and have had to pay a ll fine as the result of violating the ordinance.

bituary Notes.—Dr. DAVID L. WALLACE of New-, N. J., died of pneumonia after a brief illness February 29. He was born in Newark in 1851 was a graduate of the Bellevue Hospital ical College in the class of 1875. He was for y years a member of the Newark Board of lth and was chairman of the City Hospital Comtee.

r. THEODORE YOUNG KINNE of Paterson, N. J., of heart disease on March 4. He was born in , and was for a time a cadet at West Point. soon resigned from the Military Academy and up the study of medicine, graduating from Albany Medical College in 1862. The same he entered the Union Army as assistant surn of the One hundred and eighty-fourth New k Volunteers, and later was transferred to the ical corps of the regular army. After leaving army in 1867 and entering private practice ecame a convert to homœopathy. He was once ident of the American Institute of Homœopy, and at the time of his death he was a memof the board of censors of the New York Homœoic Medical College and consulting physician St. Mary's Hospital, Passaic. He was twice ident of the Paterson Board of Health.

r. HOWARD C. RUSSELL of the United States ine Hospital Service died on March 2 at the ine Hospital, at Stapleton, S. I., from pneuia. He was born at Washington, D. C., and educated and obtained his medical degree he University of Pennsylvania. He was apted to the Marine Hospital Service on July 1, , and served at various hospitals of the service he South and lake coasts until 1902, when he transferred to the hospital on Staten Island.

r. FRANK E. BAKER, ex-Superintendent of the ark City Hospital and a practising physician, in that city on March 1, aged forty-eight rs. Death was due to injuries sustained by ig upon a slippery pavement on the night of ruary 8 last. Dr. Baker was a graduate of the ege of Physicians and Surgeons of this city he class of 1882.

Dr. W. W. HIGHLANDS, the oldest practising sician in Hamilton County, Ohio, died on March at his home in Newtown, at the age of eighty-one rs. He was a graduate of the Medical College Cincinnati, Ohio, in the class of 1850. He was a eon in the Union Army, a member of the o Legislature in 1883, and had been in the prace of medicine for fifty years.

Dr. MOSES D. KNIGHT died at his home in Clinton, J., on March 6, of disease of the heart, at the age seventy-one years. He was a graduate of the dical Department of the University of Pennsylnia in the class of 1861. He is survived by his low and two sons, both physicians, one practisg in Clinton, the other in Ambler, Pa.

Obituary.

OGDEN CURTIS LUDLOW, B.Sc., M.D.,

NEW YORK.

DR. OGDEN CURTIS LUDLOW died at his home in this city on March 2 from typhoid fever after an illness of nearly four weeks. The attack was not apparently a very severe one and the patient was believed to be doing well until near the end, when a fatal hemorrhage occurred, and his death was therefore a great shock to his friends.

Dr. Ludlow was born on Staten Island and was a grandson of the late S. R. Smith, after whom the S. R. Smith Infirmary at New Brighton was named. He was educated at the College of the City of New York, from which he was graduated with the degree of Bachelor of Science. His medical degree was obtained from the New York University Medical College in 1883. He was a member of the American Medical Association, New York State Medical Association, New York County Medical Association, of which he was secretary, the Medical Society of the County of New York, and the Society of the Alumni of St. Luke's Hospital, and was attending physician to St. Joseph's Hospital.

Dr. Ludlow was a practising physician of more than average ability, skilful in diagnosis, sound in judgment, most happy in his therapeutic intuitions, and tender withal and full of charity for the suffering. In addition he was a medical reporter of rare discrimination, always seizing unerringly upon the important points in a paper or discussion, and presenting them in a way to impress and interest the reader. He was for many years on the staff of the MEDICAL RECORD, contributing the greater number of its society reports, local, State, and national. In this work he came in contact with many members of the medical profession throughout the country, and won among them hosts of friends, who held him in warm esteem for his endearing personal qualities and honored him for his attainments. To many of those, as to his associates on the staff of this journal, the sad notice of his untimely taking off will cause a sense of personal bereavement and excite feelings of the most sincere and heartfelt sorrow.

A Case of Acute Pancreatitis.—George Halley reports a case with operation and death. The difficulty in this case was, as usual, that of coming to a diagnosis before operating, which the severity of the symptoms and the consequent anxiety on the part of the patient demanded. As in many reported cases of acute pancreatitis, most of them having been diagnosed on the operating table, or at the postmortem, acute intestinal obstruction seemed the most likely alternative in this case because of the persistent vomiting and the constipation, which, owing to the absence of trained nurses, one could not be certain was absolute, or that the injections prescribed had been properly given. If the symptoms were due to obstruction, the cause of it must, from the character of the vomited matter, have been high up. The previous history of the passage of gallstones suggested the possibility of obstruction at the orifice of the common bile duct and pressure on the bowel. The suddenness of the onset of the attack, the persistently severe character of the pain, and the seat (the epigastrium) of the pain, seemed to point to some other cause. Unfortunately no information could be obtained from abdominal palpation on account of the thickness and the rigidity of the abdominal walls. The symptoms were too severe for biliary colic to explain everything. The later recurrence of the symptoms with unabated severity clearly indicated that operation was imperative.—*Scottish Medical and Surgical Journal.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LEAGUE AND ORDER OF MERCY—WINDSOR HOSPITAL—SPLENIC ANÆMIA OF INFANTS—APPENDIX DISEASE—UNRUPTURED TUBAL GESTATION—HOSPITAL ASSOCIATION—ARMY REORGANIZATION—PATHOLOGICAL STUDENTSHIPS—SIR S. WILKS—DIPLOMA IN TROPICAL MEDICINE—OBITUARY.

LONDON, February 19, 1904.

THE League of Mercy has maintained a place among the chief topics of the week notwithstanding the overwhelming importance of the war news. This is due to a Royal Fête held on Monday and Tuesday in aid of the league. Some disappointment was felt at the unavoidable absence of the King and Queen, but the Prince and Princess of Wales were present on both days, and the number of distinguished persons who attended was great. You may remember that this league was founded four and a half years ago by Royal Charter to promote the objects of King Edward's (then the Prince's) Fund for London. The King is now patron of the League and Sovereign of the Order. The Prince is Grand President, and the Princess Lady Grand President. The organization is extensive, and has handed over £32,000 to King Edward's Fund. The "Order of Mercy" was instituted in connection with the League, and consists of a red cross surmounted by the Prince of Wales' feathers, and having in the center a group of figures representing Sir Joshua Reynolds 'o "Charity." The "Order" is conferred by the King as a reward for distinguished personal service only in behalf of the league or in connection with the relief of suffering or distress. There is also a Samaritan Branch for ladies who visit patients, arrange for placing them in convalescent homes, and help by entertainments or other ways to brighten their lives.

Yesterday Prince Christian took part in the annual meeting of the Windsor Royal Infirmary, of which he is President, when a committee was appointed with His Royal Highness as a member to consider the desirability of erecting a new hospital, the demands on the present building being too great to cope with.

The malady commonly called splenic anæmia of infants until 1889, when von Jaksch claimed for it a distinct entity, came in for discussion at the Medico-Chirurgical Society on the 9th inst. The old name is perhaps still most generally used in this country, though a few admirers of German work follow von Jaksch. Is it really *sui generis*, or only a complication or sequel of severe anæmia in infantile patients? Drs. J. H. Drysdale and H. Thursfield submitted a paper advocating the former view. They relied on the characteristic symptoms in support of their opinion. These are profound anæmia of gradual onset and chronic duration, such enlargement of the spleen as is seen in no other form of infantile anæmia, except in the rare cases of true myelogenic leukæmia; tendency to petechial hemorrhages; constant peculiar changes in the blood. To determine the precise change a number of examinations was made, and the results compared with other severe cases of anæmia. Tables were appended giving (1) the cases on which the paper was based; (2) detailed account of the blood examinations; (3) résumé of blood examinations in other infantile anæmias.

Dr. Robert Hutchinson could not feel certain the disease was *sui generis*, for the pathology was uncertain, and the blood changes not distinctive. Probably both this disease and rickets which often accompanied it might be due to the same cause.

Dr. Baumann agreed with the authors of the paper that the disease is an entity, but he differed from them in several other respects, and was inclined to adhere to the old name of splenic anæmia of infants. Syphilis or rickets was present in the majority of cases, but he did not consider the splenic anæmia secondary to an disease.

Dr. Newton Pitt remarked that the condition of the blood suggested a reaction against some toxic influence rather than a disease *sui generis*.

Dr. Norman Moore said that Sir Wm. Jenner taught that enlarged spleen was commonly found in rickets, and the two conditions might be due to the same cause.

Dr. Drysdale in reply maintained that the clinical features and blood condition formed a sufficiently distinct picture to operate the disease from other anæmias. He did not think it resembled the splenic anæmia of adults.

Dr. Thursfield in reply added that splenic anæmia had never been proved to develop from any other form.

A very interesting case was related by Mr. Edmund Owen at the Harveian Society. A man of forty-five had had obscure abdominal pains for years and was a confirmed dyspeptic. Last May he had apparently some typhlitis which passed off. In August his doctor sent him to Mr. Owen, who, on examination, per rectum, found a hard tender tumor at the base of the bladder, not prostatic, but closely adherent to the gland. On opening the abdomen and working continuously among adherent intestines he came at the bottom of the recto-vesical pouch upon a tightly fitted abscess, the walls of which were composed of the rectum behind, prostate below and bladder in front. A kinked piece of colon formed the roof. To the right of this abscess was the end of the appendix, closely adherent to the base of the bladder, and inflamed and ulcerated. The appendix was removed, the cavity of the abscess wiped out with swabs of dry absorbed wool and the pouch drained. The peritoneum showed itself proof against bacillus coli but a fortnight later the surface wound became infected causing severe cellulitis, and large arterial branches twice burst out bleeding, the patient being in great danger from this secondary hemorrhage.

Mr. Owen suggested that probably his patient at some time had had a mild attack of inflammation, which fixed the long appendix in the pelvis, and that the more recent attack of pain was a further inflammation resulting in abscess.

Perhaps if an operation had been done on an early attack the risks would have been very much less. Mr. Owen declared that the more appendix disease he sees the more convinced he is of the dangers of delay, and the best thing for a patient is to submit to operation without delay.

At the Obstetrical Society a specimen of unruptured tubal gestation exhibited by Mrs. Scharlieb excited admiration. It was beautifully preserved and mounted. The embryo was of twenty-four to twenty-eight days development.

Dr. Cullingworth said the number of cases operated on before rupture is still so small that it is desirable to record every case. The diagnosis is always difficult, more so when, as in this case, the gestation was too early for a history of missed menstruation.

Mr. Doran thought, as a considerable proportion of tubal abortions occurred about the second month, probably a still larger number of tubal pregnancies took place and terminated earlier without symptoms. But this might be otherwise. The tube might be competent to bear the ovum up to a certain size. Much is known about early tubal gestation, but the clinical features should be more carefully studied. Dr. Cullingworth has indicated as a cardinal symptom the discharge of dark blood observed by older writers, but not correctly interpreted. Hemorrhages are probably never absent.

The army reforms—if so the changes may be properly termed—are, to say the least, as defective as many of the previous reorganizations. They quite ignore the medical service. This is an old folly, and the fruits of it were seen in South Africa. We are to have an army council on the lines of the Board of Admirality—a plan which is commended by many. The council is to be the "supreme administering body" of the army. But it has no representative of the Medical Service to advise it. Mr. Brodrich put the Medical Director on his Army Board. But Mr. Arnold-Forster gets rid of that official and on receiving a remonstrance says the council is not a representative body, so there is no need for a representative of the profession. Perhaps not, but there seems an urgent need for some one skilled in sanitation and military surgery and medicine, if the horrors caused on former occasions by ignoring the doctors are not to be repeated.

Mr. Bryant presided on Wednesday at the annual meeting of the Hospitals Association. The report of the council stated that three general meetings had been held at which useful discussions had taken place, especially as to the removal of some hospitals from their present sites. One hospital has decided to remove, and the council hoped the scheme would be well supported. At another meeting a resolution was passed disagreeing with the Committee on Nursing appointed by the Local Government Board, and asking the President to receive a deputation. Mr. Long declined a deputation, but promised careful attention to the subject. The ambulance service was also reported on. The present ambulance service for London is privately supported and consists of fifty-five stations at hospitals, fire stations and other places. This is done for about £350 a year. It is hoped the County council will take up and complete the service. They will not do it with the same economy.

Mr. Philip F. Walker has founded and endowed a studentship in pathology at the University of Oxford

His brother, Mr. Jno. Lucas Walker, was the founder of the similar endowment at Cambridge University.

Sir Samuel Wilks has undergone an operation for appendicitis and is doing remarkably well. Many of us felt much anxiety for the result to our eminent physician, for he is nearly eighty years of age. We all wish him a rapid convalescence and more happiness in his retirement—which has been so acutely interrupted.

The University of Cambridge has decided to give diplomas in Tropical Medicine, and the first examination will be held in August next. All registered practitioners are eligible for the examination on presenting proofs of study of the subject. The recognition of these proofs seems liberal. As evidence of study, candidates may submit any dissertation or record of work done.

The death is announced of Dr. Porteous, who was medical officer of Sir John Ross' expedition in search of Franklin in 1850. He served in the Navy as Assistant-Surgeon, and had medals for the Baltic and other expeditions.

Dr. Milne Murray, the Edinburgh gynecologist, died on the 14th. He had been out of health for several months, but it was hoped he would recover. The end was, therefore, rather unexpected.

Dr. David T. Playfair died on the 1st inst. from heart-failure. He had suffered from a cardiac affection for some years, and of late it had become more urgent. He went to Bournemouth to rest, but there the end came. He was only forty-eight years old. He was an Edinburgh graduate, and had practised a long time at Bromley, Kent, where he was surgeon to the Cottage Hospital.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PRESIDENCE OF THE PLAGUE—STAMPING OUT OF CHOLERA—INFANT MORTALITY—PERILS OF CHILDHOOD—A CAMPAIGN OF EDUCATION BY THE SANITARY AUTHORITIES.

MANILA, January 10, 1904.

The report of the Commissioner of Public Heath, for the month of December, 1903, states that there were but two cases of plague during the month, both in Filipinos, who were dead when found. The Chinese population has been largely protected against this disease by anti-plague inoculations. There were eleven deaths from cholera during the month, this being a gratifying reduction from the twenty-six deaths from this cause in November, the one hundred and eighteen in October, and the two hundred and sixty-three in September. It is expected that with the continuance of the present measures the infection of cholera will be eradicated from the city in the month of January. Of the total deaths reported in the city during the month, 60.6 per cent. occurred in children who had not completed the first year of life; of the total deaths occurring among the Filipino class of the population, 65.8 per cent. occurred among children less than twelve months of age. Two new free dispensaries were established during the month and put into operation. As so far these institutions have been regarded with some distrust by the class of the population it is most desired to reach, special efforts are being made to popularize their use by the indigent.

The question of infant mortality is being given much attention by the sanitary authorities, the death rate among infants being extremely high. This is particularly the case at the present season of the year, which has been unusually cool. Infection of the cord, insufficient clothing, and improper feeding are the main causes of this mortality. The cord is ordinarily manipulated with unwashed fingers, cut with a dirty knife, and tied with unclean cord. Any piece of cloth, soiled or otherwise, is regarded as suitable for dressing the cord by the lower classes, who sometimes use wood ashes as a dry dressing. If the cord does not drop off within a week it is often forcibly removed by the native mother, who also massages the child's abdomen and the navel wounds to prevent colic. With the germs of tetanus almost omnipotent, it is not strange that the mortality from this disease among the new-born is high. The newly-born child is often subjected to exposure that the mother or father would not think of imposing upon themselves. The adults are reasonably well clothed with one or two thicknesses of cotton cloth, but the customary garment of the young child is a single shift of native gauze cloth reaching scarcely to the hips, in order to avoid being soiled by the discharges. Such a gauze garment is practically no protection against cold, and in the country districts even this single shirt is conspicuous by its absence, and until the age of about six or eight years the average child of poor parents, outside of Manila, wears little, if any, clothing. The usual sleeping arrangements consist of a straw mat laid over a bed or floor of split bamboo, with perhaps a cotton spread as cover. The young child is given no special consideration in the matter of sleeping facilities, and is as likely as not to be left in a draught to be chilled by the winds of cool rainy nights. Under such circumstances, the results of chilling, as seen in bronchitis, pneumonia, and congestive diarrhœa, are a potent factor in raising the death rate among young children during the cool season of the year, when they are subjected to an ordeal of exposure from which a large portion of such children are unable to survive. The insufficient clothing of the children appears to be due to ignorance, poverty, and a disinclination to perform the extra laundry work which, the washing of clothing soiled by the infant's discharges would require. It is an almost universal custom through the islands to leave children practically unclothed, and custom among the Filipinos has almost a religious sacredness, which the native is unwilling to change or have interfered with. While the native mother is apparently as fond of her child as a mother of any other nationality, she is loth to break away from local ideas and customs in respect to its care, even at the expense of the health and life of her infant.

Should the child survive the dangers of tetanus and exposure, it will arrive at a period when its diet will either be insufficient or improperly constituted. Children appear in a Filipino household with clockwork regularity, and the spectacle is common of a mother advanced in pregnancy with a nursing child at the breast. Obviously her system cannot stand this double drain, and her milk becomes scanty and of deficient quality, and the nursing child is defectively nourished. Mothers also nurse their children too frequently; and should an infant develop diarrhœa the common idea is that it should be nursed as often as it will take the breast, so that the digestive organs are given no opportunity for rest. It is also customary, if the flow of milk from one breast is not large, to consider the milk of poor quality, and allow that breast to atrophy from disuse. If the mother is unable to nurse the child properly its early demise is probable. The Filipino woman does not take kindly to the position of wet nurse if her own child be alive. Fresh milk is difficult to procure, and the use of condensed milk is not well understood. Both fresh and condensed milk are largely beyond the reach of the poorer classes. Occasionally a little carabao milk is obtainable, but it is not often given diluted; is too rich for the infant, and is procured and kept under such conditions as to ensure its infection with pathogenic germs. A few goats are kept, and when the milk of these is used for nursing infants the latter are often allowed to such direct from the dirty teats of the animal, whose milk, also, is too rich to be well borne. When the mother cannot nurse the child, and in all cases, at a relatively early period of life, the infant is fed on rice water, broths, fish soup, and corn porridge. Fruits are given early, and the sight of a half-green, mango, contaminated by dirty hands, held to the mouth of a toothless babe, is not uncommon. The child is given the ordinary diet of the family as soon as it will take it, while its drinking water is always unsterilized, and drawn from a source which, in the Philippine Islands, is almost invariably contaminated. The food given is often poorly cooked, or allowed to stand until fermented, and the digestive organs of the child are overtaxed with material which it is not only unable to assimilate, but which is probably contaminated with the germs of disease. Indigestion, diarrhœa, malnutrition, convulsions, and death are logical sequelæ, which too frequently follow. Pigs, dogs, cats, chickens, and babies share the limited accommodations of the native house together, and as the child is allowed to lie on the dirty floor and ground and is never washed its chances of escaping infection with intestinal parasites are not great.

If the child survives the many dangers of the first year of existence its expectation of life is excellent. The defectives have been eliminated by vicissitudes which only those of most robust constitution have been able to resist, and these latter represent the survival of the fittest. The constitutionally weak are unable to survive in the struggle for existence, and succumb to conditions dependent on ignorance, poverty, and custom; conversely, the child who has been able to maintain itself through the first two years of life will be found to be strong, sturdy, and resistant to disease. A further cause for a high infant mortality is found in the dearth of physicians, and the unwillingness of the people to employ them when obtainable, except when the illness is so far advanced that the child is beyond medical aid. Every old woman is an amateur doctor, whose recommendations do more harm than good. The most extraordinary measures are adopted in the case of sickness, and applied to the helpless infant, as dressing the umbilical stump

with a paste of stewed fish, or burning the child with hot cocanut shell to cure convulsions.

The sanitary authorities appreciate that effort to reduce the general death rate should best be directed toward the reduction of infant mortality. To this end they are pursuing a campaign of education, and are issuing circulars of instruction, in the various native languages, on the care and feeding of infants, by the thousands. In Manila, one such circular is placed in every family having young children and sent to the parents of every child whose birth is reported. Plans are also being made by which the mother of every child brought for christening will also receive such a circular. New dispensaries have been established, additional municipal physicians and midwives employed, and every effort made to popularize their use by the indigent. Parents in poor circumstances may receive free a yard of Canton flannel, sufficient to make two warm shirts for an infant, at any municipal dispensary. Plans are being prepared for a free maternity hospital and training school for midwives. All these measures should ultimately have their effect in reducing a mortality among infants which is as appalling as it is theoretically unnecessary.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 18, 1904.

Scientific Aspects of Moderate Drinking.—Francis Gano Benedict declares that it is evident that individuality and physical condition play a very important *rôle* in determining what is commonly meant by excess. Moderation for one man may be decided excess for another. From careful research it has been determined that habitual indulgence in alcoholic liquors beyond the most moderate amounts help to shorten life proportionally to the degree of indulgence. In life insurance companies there seems to be much more importance attached to the applicant's relation to the use of alcoholic liquors now than twenty years ago. In general it may be said that alcohol diminishes all forms of mental activity. The use of moderate quantities of alcohol has a strong tendency to lead to its excessive use. The habitual use of alcohol in any amounts should be discountenanced. Special pains should be taken to show the young man that any use of alcohol, even though it be occasional, must be regarded as contrary to scientific teachings. Alcohol even in small amounts retards the physical and mental growth of youth. The habit-forming tendency of alcohol is a factor in the moderate use of alcohol that must be taken into serious consideration. It is not unreasonable to conclude that there is a real danger from the habit-forming tendency of alcohol which should not be overlooked in any consideration of the use of alcohol.

Slipping or Recurrent Dislocation of the Patella, with the Report of Eleven Cases.—Joel E. Goldthwait states that the above condition is seen almost entirely in girls or women, and is due, in large part, to the fact that the line of pull of the quadriceps extensor muscle is not straight, this feature being increased in its effect by an unnaturally long patella tendon, knock knee, or an imperfectly developed articular surface at the end of the femur. The chief point in the treatment consists in the correction of the angle in the line of muscle pull so far as it is possible. If the patella tendon is long, so that in complete extension the patella is drawn above the outer ridge on the trochlear surface of the femur, it should be shortened. In shortening the tendon, it is better at the same time to change the attachment of a part of the tendon, thus making the line of pull more nearly straight. In the majority of the cases the attachment of the patella tendon is distinctly farther to the outside than normal. The most satisfactory treatment is an operation in which the outer half of the patella tendon is reattached to the tibia well to the inside of the tubercle. The operation consists of a longitudinal incision four or five inches long, extending from just below the tubercle of the tibia upward. Through this the patella tendon is exposed and split in halves, antero-posteriorly, throughout its entire length. The outer half is then cut from its attachment, passed under the remaining part and attached to the periosteum together with the expansion of the sartorius muscle at the inner side of the anterior surface of the tibia. If it is desirable to shorten the patella tendon the attachment can be so made that the patella is drawn down as much as is desirable, but as this causes much tension upon the new attachment, a hole should be drilled in the bone at the point of attachment, through which the suture is passed which holds the tendon. The carrying of the free part under the other is of importance, as in this way the patella is tilted, the outer part being drawn downward, and impinges more firmly against the outer ridge of the articular surface of the femur during muscular contraction, so that the danger of displacement is materially lessened. The attachment is ma with strong silk, quilted through the tendon. T wound is tightly closed and the leg fixed in a plas bandage for about six weeks.

Journal of the American Medical Association, March 5, 190

A Report of Ten Cases of Pneumothorax Occurring Pulmonary Tuberculosis.—J. W. Trask, who practises New Mexico, believes that pneumothorax is a more co mon incident in that locality than it is elsewhere, and th the prognosis is less hopeful. If this be so, one wo naturally look to the altitude of this locality (6,150 fe as a possible explanation, inasmuch as it requires mo air to be respired to oxygenate the blood, and co quently a greater amount of lung or a greater activi of the same amount as would be needed in less eleva regions, and therefore any great disturbance of the respi tory tract, such as occurs in pneumothorax, is not w borne. But the drawing of conclusions as to why so la a percentage of the deaths at this place have been to this cause must be deferred until more cases and larger series can be reviewed.

Headache from Non-suppurative Inflammation of Accessory Sinuses of the Nose.—C. M. Robertson ca attention to headache from disturbances of air press in the accessory sinuses of the nose. Any closure of natural sinus outlet leads to diminished intrasinus pr sure owing to the absorption of oxygen by the bloo vessels of the mucous lining, and as a result the lat swells. Later there may result a serous outpouring in the sinus and an engorgement of its lymph channels. other words, the condition is analogous to non-suppurati otitis from closure of the Eustachian tube. The sym toms vary according to the time the sinus remains clos the prominent one being headache. Occasionally t tissues of the middle turbinate may contract and so enla the openings under its lee that the symptoms ameliora The usual objective signs of empyema are absent. Th is no mucopurulent discharge and transillumination negative. Treatment should be directed toward t establishment of free drainage.

Chronic Adhesive Sclerosing Peritonitis, or Pla Peritoneal Sclerosis.—H. G. Wetherill reports a case of t nature, the lesion being an extensive subperitoneal fibr infiltration or sclerosis without ascites and without se fibrous or fibrino-purulent infiltration. The points interest in the case are summarized by the author as f lows: (1) The rareness of the disease. (2) The fail on this continent, generally to recognize and fully to scribe it though it has been long and well known abro (3) The pathognomonic sign—inability to unite a shri ing peritoneum once divided during the course of operation, which, so far as the author is aware, he is first to observe and describe. (4) The essential chronic of the disease, as indicated by the long-standing symptom otherwise unexplained, and by the shrinking and retr tion of the peritoneum at the first operation, sixte months prior to her death, which proved the previ existence of the malady, and that it was not directly indirectly the result of the operation. (5) The gr importance of covering all denuded surfaces when bef or during an operation chronic adhesive sclerosing p tonitis is diagnosed. (6) The characteristic subperiton connective tissue hyperplasia, which is the patholog feature of the disease. (7) The shrinking or contract of the peritoneum caused by it, the clinical feature. The possible significance of a somewhat similar pathologi process taking place in the skin coincident with unus gastrointestinal symptoms otherwise unaccounted f (9) The possible diagnostic value of this syndrome. (The danger of serious sequelæ incident to its surgi treatment.

Medical News, March 5, 1904.

Suture of the Omentum to the Parietal Peritoneum (E plopexy) for Ascites.—Joseph H. Branham reports a c of cirrhosis of the liver with ascites. At operation, omentum was found to be adherent to the parietal pe toneum on each side, the adhesion being very vascul showing the effort of nature to form collateral circulati About six months after the operation, during which ti the patient's health had been greatly improved, pleu effusion with no ascites developed. This points stron to good collateral circulation for the portal system. T chest was aspirated and the patient improved. Th showed that better functioning of the liver and intesti organs followed the operation.

The Pathological Anatomy of Shiga-Bacillus Infection the Intestine in Infants.—John Howland gives a report autopsies made at several of the large hospitals for infan The Shiga-bacillus was proved to be present in the gre majority of cases by an examination of the stools, but i seven cases it was obtained post mortem by scraping th mucous membrane of the colon, and in three cases it wa

ytained both ante mortem and post mortem. The organ- as found in all these cases corresponded in all particu- to the type known as the "acid" or "Harris" or lexner-Maiula," organism. The writer adds that the ions in the intestines in children, as in adults, must for present be conceived to be of two kinds, first those to the action of the dysentery bacillus, and second of products of this and perhaps other organisms. In there is a conformity in the condition found in chil- and in adults. In the cases of the writer, the lesions d were not usually typical pseudomembranous inflam- ions, the pseudomembrane appearing either on the sur- of ulcers or as isolated areas upon the mucous surface he intestine. This seems to be in contrast to the ges described in adults. The involvement of the soli- and agminated lymphatic structures in children is a er distinction, for the same structures in adults usu- escape participation in the pathological process. The r concludes that there are comprised under the lesions iated with the Shiga-bacillus all grades and types of bœal disease as distinguished by clinical symptoms pathological findings, and no particular type is distin- ed from the others by a special etiological origin.

got in Alcoholism, Morphinism, and the General Class ug Habit Cases.—Alfred T. Livingston describes his od of treating these cases. First, he wholly and diately discontinues the use of the narcotic, and so ges that the patient is absolutely prohibited any to the drug or to any other that could be regarded substitute. The application of ergot is then at once n. At the same time a mercurial purgative is given, wed in a few hours by a sufficient saline to assure pt purgation. The ordinary meals are discontinued abundant fluid and easily digested nourishment is every three hours. No nutrition prepared with ol is used. The bowels are kept open once a day— two or three times. The frequency of application e ergot will depend upon the degree of addiction, and the general condition of the subject when the drug discontinued. In general, the range would be from to three doses a day to one every two hours in the me cases. A dose is one-half drachm of extract of . The writer has in no case after the first forty- hours had a request from a patient for the ac- med drug or a substitute. The writer is radically sed to the "tapering off" plan, but he suggests cedure for this treatment which may be followed out e extreme cases of morphine or opium addiction. two of the ergot hypodermics daily, a fractional part e drug is given. This dose is daily reduced till about ighth day, when the morphine is discontinued.

New York Medical Journal, March 5, 1904.

stdiphtheritic Paralysis of Accommodation with Re- of a Case.—According to A. Bray, this sequel of theria occurs in about 10 per cent. of all cases of the se. This paresis of accommodation is never a com- paralysis, and is always bilateral, affecting both eyes ltaneously. Its degree has no necessary relation to everity of the diphtheria. It never follows a simple a. It is generally believed that the condition is a heral neuritis, but some contend that it is due to local latory disturbances. The latter theory is strength- by the usual rapid recovery seen in these cases. The t of the paresis depends upon the refractive condition e patient. The diagnosis is, comparatively speaking, —the history of an antecedent diphtheria with distant n clear and normal, and vision for near objects indis- ; add to this a clear medium of refraction and an almoscopic examination negative, and the diagnosis rtain. Prognosis is in most cases favorable, complete overy coming on in from two to three months. Glasses uld not be prescribed except in high degrees of hyper- . Fresh air, good food, absolute rest, and tonics con- ute the proper treatment.

hrombosis of the Jugular Veins in Pulmonary Tuber- sis.—A case of this nature is reported by C. J. Aldrich, has found reports in literature of nine similar cases. regards the accident as far more common in the late es of the disease than is supposed, and not so rare in the y stages as we assume. Causes have been erosion of s from external pressure, adhesions, or tuber- us lymph glands. and phlebitis from internal ors. Other possible causes enumerated by the ter are: (1) Presence of microorganisms or irritat- compounds in the blood; (2) alterations in the el wall; (3) changes in the normal constituents of the od; (4) alterations in the movement of, and loss of nal pressure in, the blood stream. He then discusses mode of action of these various causal factors. His n case was that of a woman aged twenty-seven years in last stages of pulmonary tuberculosis. There was the left internal jugular vein, a thrombus which extended through the subclavian vein down the axillary into the basilic. Two weeks later a similar thrombus formed on the right side, Death was caused from cerebral sinus thrombosis from extension of the deposit in the right internal jugular. No autopsy was held.

Bilateral Excision of the Superior and Middle Cervical Sympathetic Ganglia in Five Cases of Epilepsy.—The cases are reported by S. D. Hopkins, who states that the function of the cervical sympathetic is to control the muscular action of the cerebral blood-vessels; to transmit impulse from the stomach, intestines, and lungs, and to innervate the dilator muscles of the pupils and also the unstriated muscles of the lids. The most probable theory of epilepsy is that there is some circulatory disturbance in the brain. The cervical sympathetic ganglia contain the vasoconstrictor nerves, and the excision of these structures prevents vascular spasm, therefore, the lumen of the blood-vessels is permanently dilated, which increases the nutritive supply to the brain cells, and as a result of this, toxic elements are the more readily removed from the brain tissue. Of the cases reported one was apparently cured; in the others the number of attacks was greatly diminished. The author details the symptoms following the operation; many of these are transitory, but we may permanently expect ptosis, myosis with paresis, and lessened tension with recession of the eyeball.

American Medicine, March 5, 1904.

Diphtheria of the Vagina with Secondary Involvement of the Mouth, Rectum, and Skin.—Thomas W. Salmon describes this unusual case. The patient, a woman, was fifty-five years old. She was admitted to the hospital with acute melancholia. As cases of diphtheria had occurred in the building in which she resided, she was given an immunizing dose. A culture was taken from her throat before she had shown any evidences of illness. No diphtheria bacilli were present. About a week later, small white patches were noticed on the labia minora and several near the meatus. Diarrhœa was present and continued till her death. A few days later diphtheria bacilli were found in the throat. Patches of membrane developed on the lips, the tongue, and the hard palate. A dense white membrane now completely covered the vulva, the vagina, and the visible mucous membrane of the rectum. An abrasion on the cheek became covered with a typical pseudomembrane. Cultures from these various lesions showed typical diphtheria bacilli. Autopsy was not permitted.

A Case of Acute Leukæmia with Death Due to Rupture of the Spleen.—Joseph L. Miller reports this case. The patient was a man aged twenty-four years. His illness began with severe abdominal pain, especially after eating, and anorexia. These symptoms continued with intermissions for five weeks. He then had pains in the epigastric and lumbar regions, and marked flatulency and malaise. The spleen was barely palpable. The abdomen was uniformly distended. Under light diet and free catharsis, the patient improved, but three weeks later took to his bed. He then suffered from severe pain in both hips, and in region of the crest of the ilium. A few days later the spleen, on deep inspiration, extended two fingers below the costal arch, smooth and soft. The blood examination showed the following features: Leucocytes, 50,000; erythrocytes, 2,800,000; hæmoglobin, 48 per cent. Differential count showed 200 leucocytes; 4 per cent. of small lymphocytes; 84 per cent. of large mononuclears; 3 per cent. of eosinophiles; 1 per cent. of myelocytes; 8 per cent. of polymorphonuclear neutrophiles. There were numerous nucleated reds, chiefly megaloblasts, many of these showing mitotic figures. Two days later the patient died. Autopsy revealed two tears on the anterior superior surface of the spleen. There was also a small circular area of necrosis in the organ.

An Original Operation for Complete Laceration of the Female Perineum.—C. E. Ristine makes first an outline incision which varies in shape and length to conform somewhat to the extent of the laceration, with special reference to the rectal tear. Following the outline incision, he begins denuding the mucous membrane and cicatricial tissue, included in the outline from the highest point in the vagina, carefully dissecting down to the apex of the rectal tear, and laterally from the incisions down to the margin of the rectal tear. These lateral incisions should expose the ends of the sphincter muscle. The frill is then inverted into the rectum and is drawn well down below the anal margin with tissue forceps, which are left attached, for further traction if required, when adjusting vaginal or perineal sutures. The ends of the sphincter muscle are drawn out and fastened, and through this muscle, near its ends, is passed a chromicized or cumolized catgut suture. Gentle traction on this suture will approximate the ends. While the traction is continued, a silkworm gut suture is

gives a reaction like that of homologous serum, but causes the red cells to shrivel and assume a polygonal form instead of the thornapple shape usually produced by the addition of human blood.

French and Italian Journals.

Alopecia Areata from Trauma.—Florio Sprecher describes a case of alopecia areata in a girl of six years, following an injury to the scalp. There was no hereditary nervous condition, and all the other children of the family were healthy. No relative had ever had the disease. The patient was well developed and robust and not of a nervous temperament. A year previously she had received a blow with a stone on the right side of the head, causing a small lacerated and contused wound which gave a great deal of pain. The wound healed in six or eight days. The alopecia began seventeen days after the wound was received, and in three months had increased in area to the size of the palm of the hand, over the temperoparietal and frontolateral region of the right side. The lesion had all the characteristics of a true alopecia areata.—*La Riforma Medica*, February 3, 1904.

Ulcer of the Duodenum.—Chavannaz operated upon a patient who had never before this attack presented very marked digestive disturbances. The first warning of trouble was abdominal pain. This became more acute on the right side. The patient was unable to work and entered the hospital. The skin was pale, the pulse small and 120 per minute, and the abdomen was somewhat retracted. The greatest pain was between McBurney's point and the costal border. The diagnosis was made of peritonitis consecutive either to appendicitis or to ulcer of the duodenum. Laparotomy disclosed the latter condition. The patient died the same evening. At necropsy there was found an ulcer the size of a small pea, near the pylorus. —*Gazette Hebdomadaire des Sciences Médicales*, February 14, 1904.

Actinomycosis and Epithelioma of an Inflammatory Form.—Le Dentu makes this interesting report: Although actinomycosis is relatively frequent in certain parts of France it is rarely found in Paris. A case was recently observed presenting the clinical characteristics of the affection. The case was diagnosed as actinomycosis by various students who had had the opportunity of examining typical cases. Search for the specific granules was fruitless. On account of a suggestion that these elements had been destroyed by secondary infection, an exploration, a sort of curettage was made, to facilitate the examination of new tissue. Histologically, this was shown to be an epithelioma of inflammatory form. Le Dentu concludes that the diagnosis should be made only in the presence of the characteristic granules of the parasite.—*La Tribune Médicale*, February 12, 1904.

Acute Glaucoma Treated by Adrenal Extract.—Grandclément reports the excellent results he has had in the case of a patient of thirty-seven years, suffering with a very severe attack of acute glaucoma. His treatment consisted in the instillation of adrenal extract of the strength of 1 to 5000, into the glaucomatous eye every half hour for three consecutive days. This is the first case of the kind that the writer has treated systematically by this method without iridectomy. The course of this case and the results obtained have convinced the writer that he can in the future probably cope with the various forms of glaucoma by means of simple instillations of adrenal extract, as well if not better than by the classical operation of iridectomy. This would be most satisfactory, considering that iridectomy is a very difficult operation in glaucoma—very painful and without satisfactory results in nearly half of the cases. The operator should aim to make the instillation sufficiently often and long, to dry up at once the secretion of intraocular liquids and to cause the hypertension of the eye to subside.—*Lyon Médical*, February 14, 1904.

Cyst of the Parovarium; Rupture of the Fallopian Tube; Hæmatocele.—This case came into the hospital in the service of Courtin. The patient was a woman aged thirty-five years. She had no history of illness before the present attack. She had given birth to three children, but had never had a miscarriage. Five months before her entrance to the hospital, there was rather an abundant hemorrhage, composed of fluid blood with no clots. There was no pain. Two months before she was attacked suddenly one morning with violent pain in the lower abdominal region. This attack was so severe that the patient had to stay in bed. Peritoneal symptoms developed—distention of the abdomen, vomiting, hiccough, constipation, and fever. These symptoms gradually grew less, but the patient had not been able to attend to her daily occupations. Internal examination revealed a liquid tumor to the left of the uterus. Curettage showed the existence of interstitial fibromata in the uterus. Laparotomy was performed and a large retrouterine hæmotoc was discovered. Drainage of the posterior cul-de-sac instituted. The right ovary was cystic; the left was fil with small cysts containing a bloody liquid. The left t was ruptured. There was a serous cyst of the broad l ment, on which was lying a large hæmatocele. explained the rupture of the tube.—*Journal de Méde de Bordeaux*, February 14, 1904.

Analgesia by Lumbar Puncture.—Filippo Caccia rep the use of hydrochlorate of tropacocaine by lumbar p ture for analgesia in forty-three operations, in tw seven of which analgesia was complete, in eight inc plete, and in eight absent. The operative proced were abdominal, genitourinary, anal, rectal, and in lower extremities. In the cases in which analgesia not present chloroform narcosis was much easier usual. The advantages of this method are: (1) Bec the patient is entirely conscious there is no need of a f position or of the presence of a physician immedi after the operation, as in chloroform narcosis. (2) patient is much more quiet, and is able to assist the geon by changes in position. (3) Shock is less. (4) applicable to cases of heart, kidney, and arterial di (5) Ease of transportation is greater, which is espec important in military surgery. In slight operation patient can walk a short time after the operation. Economy of time. (7) Instrumentation is simpler with chloroform. Tropacocaine is better than co because it retains its power for at least twenty-four and can be repeatedly sterilized by boiling. Analge more profound in the regions supplied by the sacro geal plexus than in that supplied by the lumbar p —*Giornale Medico del Regio Esercito*, January 31, 1

The Glycogenic Reaction of the White Blood Corpu —Giuseppe Spezia has investigated the glycogenic tion of the white blood cells in pathological condi Normal blood has no glycogenic reaction, but wi increase in the number of white blood cells within p logical limits, as during digestion and in pregnanc glycogenic reaction appears. The appearance of a genic reaction in the blood indicates an increase of corpuscles. The writer tested the blood in forty-six including bronchitis, bronchopneumonia, croupous monia, pertussis, measles, nephritis, rheumatism, etc. concludes: (1) Albuminoids, hydrocarbons, and fats important in the production of the glycogenic react the white corpuscles. (2) It may be observed phys cally in digestion. (3) It is met with pathologica the presence of leucocytes, and of phagocytes as th found in the sputum of pulmonary affections. (4) have a value in general diagnosis, but not in diffe diagnosis. (5) The distinction between intracellul extracellular glycogenesis is useless. (6) There causal relation between glycogenesis and amyloid eration. (7) Whether it be physiological or patho it bears a relation to the amount of albuminoids, carbons, and fats in the circulation. (8) The glyc reaction confers upon hyperleucocytosis a definite cal value. (9) A marked glycogenic reaction in hyperleucocytosis.—*Gazzetta Medica Lombarda*, ary 8, 1904.

Appetite Juice and the Ethics of Eating.—J. G. A reviews Pawlow's experiments on dogs, by which been proved that there are two tides of secretion gastric juice; the psychic tide, set up by the sight of by the taste of the same, and by hunger, the juice tide (the appetite juice) being relatively abundant, f for a considerable period, and having strong dig powers. The chemical tide is set up at a later peri the direct effect of the foodstuffs upon the gastric m membrane. The former is brought into activity b higher centers; taking everything into consideratio the more important. Food eaten without relish without appetite, although in itself most nutritious, lie for hours within the stomach undigested. So food eaten while the mind is diverted to other things stay for long unacted upon, or is liable to undergo d position, and, irritating the mucous membrane, may l its condition. If, therefore, dyspepsia is to be warded the food should be taken under such conditions that ev thing is directed, on the one hand, to remove the thou from the cares of daily life, and on the other to make repast appetizing, so that the palate may be tickled the flow of appetite juice excited.—*The Montreal Med Journal.*

Book Reviews.

DISEASES OF THE PROSTATE GLAND AND ADNEXA. By GEORGE WHITFIELD OVERALL, A.B., M.D., formerly Professor of Physiology in the Memphis Hospital Medical College. Chicago: Marsh & Grant Company, 1903.

This little volume of two hundred pages gives a cursory view, so to speak, of the subject, based upon the author's experience in practice and including considerable subject-matter published by him in current journals. Although considerable attention has been given to electrotherapeutics in the treatment, high-frequency currents have been omitted.

DISEASES OF THE EYE. By L. WEBSTER FOX, A.M., M.D., Professor of Ophthalmology in the Medico-Chirurgical College of Philadelphia, Pa.; Ophthalmic Surgeon in the Medico-Chirurgical Hospital. With Five Colored Plates and Two Hundred and Ninety-six Illustrations in the Text. New York and London: D. Appleton & Company, 1904.

The volume is one of 584 pages, is well printed, profusely and quite well illustrated. Many black and white cuts appear in the text, and there are five plates in colors. Many of the illustrations are in half-tone from photographs. The work is divided into twenty-one chapters, of which the first treats of the development of the eye, the second of anatomy of the eye. The diseases of the lids are first taken up, and chapters on diseases of the various parts of the eye follow in logical order. A chapter is devoted to a consideration of the Röntgen ray in locating foreign bodies in the eye, and the various methods of technique are described. A chapter is devoted to a consideration of the relation of ocular affections to general diseases and one to "The Pupil in Health and Disease." Refraction and the anomalies of the muscles of the eye are considered in chapters near the end of the book, while an appendix treats of "General Operative Technique." A formulary containing some fifty-five prescriptions and a glossary occupying about eight pages precede the general index.

Much attention is given to the operative procedures necessary in treating diseases of the eye, particularly plastic operations, which always present problems for even the experienced surgeon. The consideration of the operations on the eye is placed on a rather high level, and presents in a forcible way the individual ideas of the author.

The work is not an elementary one; while it will undoubtedly find favor among many students, it is more particularly adapted to the general surgeon and to the ophthalmic surgeon. It presents the views of one of wide experience and of decided opinions.

DISEASES OF THE NERVOUS SYSTEM. A Textbook for Students and Practitioners of Medicine. By H. OPPENHEIM, M.D., Professor at the University of Berlin. Translated and edited by Edward E. Mayer, A.M., M.D., Pittsburg, Pa. Second American Edition, Revised and Enlarged. Philadelphia and London: J. B. Lippincott Company, 1904.

This is the second American edition, being a translation of the third revised German edition of Oppenheim's well-known textbook on nervous diseases. The original work was favorably received by American neurologists and general practitioners, and the various critics have expressed well-deserved appreciation of its merit. It has become one of the standard popular works on neurology. In this American translation, the original text is followed closely, and the recent advances in neurological matters have been brought up to date. The work is divided into a "General Part" treating of the methods of examination; general symptomatology, and objective examination, and a "Special Part" consisting of six sections, respectively: (1) Diseases of the Spinal Cord. (2) Diseases of the Peripheral Nerves. (3) Diseases of the Brain. (4) The Neuroses. (5) Diseases of the Sympathetic Nervous System. Angioneuroses and Trophoneuroses. (6) Toxic Conditions with Predominating Nervous Symptoms. The new edition also contains an additional number of well-executed illustrations.

THE TREATMENT OF FRACTURES, with Notes upon a Few Common Dislocations. By CHARLES LOCKE SCUDDER, M.D., Surgeon to the Massachusetts General Hospital. Fourth edition. Philadelphia, New York, and London: W. B. Saunders & Co., 1904.

This work, which has all the features of an elaborately illustrated one on fractures, has many half tones added to the present edition, thus increasing its practical value. A final chapter on the common dislocations is also another recommendation for increased usefulness. Taken as a whole, the treatise will appeal specially to the general practitioner who desires all the necessary details of technique fully and accurately represented. This design is satisfactorily accomplished by the insertion of 688 artistic illustrations.

A MANUAL OF MEDICINE. Edited by W. H. ALLCHIN, M.D., London, F.R.C.P., F.R.S. Ed., Senior Physician and Lecturer on Clinical Medicine, Westminster Hospital; Examiner in Medicine, Naval Medical Service; Late Examiner in Medicine in the University of London for the Royal College of Physicians of London and for the British and Indian Army Medical Services. Vol. V. Diseases of the Digestive System and of the Liver; Diseases of the Peritoneum and of the Vessels of the Abdomen; Diseases of the Kidneys; Diseases of the Ductless Glands. New York: The Macmillan Company; London: Macmillan & Company, Ltd., 1904.

THE list of contributors to the fifth volume of this system comprises eleven of the best known authors in Great Britain. Each one has been selected with reference to his fitness for the special subjects treated, and it can be truly said that each has performed his task with credit. The first article treats of the general anatomy and physiology of the digestive organs, and includes the main items of interest regarding foods and beverages. Over fifty pages are devoted to these important subjects. Following this is a short article on the bacteria of the alimentary tract. The special diseases of the digestive organs are treated in detail, but in addition to the usual routine descriptions are those on general etiology of gastro-intestinal trouble with very full chapters on their morbid anatomy. The diseases of the liver, peritoneum, abdominal blood-vessels, kidneys, and ductless glands are managed in the same way and contain points and explanations usually ignored in the textbooks of to-day. Diagrams, tables, and plates are inserted where it seems necessary and serve to complete a most satisfactory compilation.

INFANT FEEDING IN ITS RELATION TO HEALTH AND DISEASE. By LOUIS FISCHER, M.D., Visiting Physician to Willard Parker and Riverside Hospitals, New York City. Third edition. Philadelphia: F. A. Davis Co., 1903.

WITH each new edition the author endeavors to improve upon the former by elaborating clinical observations and multiplying details for more efficient feeding. In the present work the subjects of feeding dyspeptic and atrophied children are treated. Also of rectal feeding in intubation cases, and of feeding children with cleft palate. A new chapter containing much practical information is added on butter-milk feeding, and also new illustrations of poor breast milk are shown as arguments for artificial and substitute food. Modified milk receives due attention in a special chapter. In many other respects it shows evidence of careful remodeling, making the work as a whole thoroughly up to date.

PROSTATIC HYPERTROPHY from Every Surgical Standpoint. By GEORGE M. PHILLIPS, M.D., and Forty Distinguished Authorities. Edited and Compiled by S. C. MARTIN, Jr., M.D.; St. Louis: Lewis S. Matthews & Co., 1904.

THE editor has selected fourteen questions bearing on the subject and submitted them for answers to forty leading surgeons of this and other countries. In this way the different views and the reasons therefor are given in a way that permits of immediate comparison. It makes a most interesting and valuable contribution to the subject of prostatic hypertrophy.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and especially prepared original articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other topics of interest to Students and Practitioners. By leading members of the medical profession throughout the world. Edited by A. O. J. KELLY, A.M., M.D., Philadelphia, U. S. A. Volume IV. Thirteenth Series, 1904. Philadelphia: J. B. Lippincott Company, 1904.

ALTHOUGH the contributors are numerous and well known, starting with Albarran of Paris, and ending with Casey Wood of Chicago, and including between these two alphabetical limits, De Costa, Duncan, Julien, Keen, Musser, Senn, Tyson, and others. Still the lack of attractive illustrations and an inferior quality, from the artistic side, in those pictures introduced, gives the impression of a slight falling off in the tone of this publication. Among the interesting chapters are those on the Treatment of Ulcers, the Injection Treatment of Syphilis, the Physiognomical Diagnosis of Disease by Duckworth, Angioneurotic Œdema, by Burnet, and Prostatic Hypertrophy, by Albarran. Under the special departments will be found many interesting short articles by well-known writers.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 5, 1904.

ROBERT T. MORRIS, M.D., CHAIRMAN.

A Case of Bone-grafting.—Dr. CARL BECK presented a man whose ulna had been crushed by machinery one year ago. A fracture of the lower end of the radius and a compound fracture of the ulna was diagnosed. Two splinters of bone were removed. A few months later when he saw the patient there was noted a prominence on the radial side and a gap on the ulnar side low down, with disturbed function. The *x*-ray picture revealed an unimpaired radius, and two slivers of bone over the anterior surface of the radius was noted. One of these was removed and the other was implanted in the gap and kept in place by means of a rubber drainage tube and a plaster-of-Paris dressing. Function was partially restored and would be much better later.

Epithelioma of the Tongue, Excision and X-ray Treatment.—Dr. C. A. MCWILLIAMS presented a woman, twenty-four years old, who consulted him a year ago last August because of excessive pain in the tongue, especially on eating. She could eat only liquid food because of the pain caused by masticating. This pain was felt down the neck and up to the ear. She had lost much flesh and was very much weakened. A lump about the size of a silver dime about one inch from the tip of the tongue was found. There was a depression in the middle, a hard border, with radiations into the surrounding healthy tissues. The teeth were in a bad condition. A diagnosis could not be made from its macroscopical appearance, but the pathological examination revealed flat-celled epithelioma. Fifteen of her teeth were removed, and, when she was in good condition, operation was performed, an incision being made from the symphysis menti to the angle of the jaw, extending down below the hyoid bone. The operation was quite an extensive one. There had been a partial facial paralysis following the operation. The submaxillary space was carefully cleaned out and the lingual triangle carefully searched, but no further lesion was found. After mapping out his course he cut wide of the growth, dividing the mucous membrane near the alveolar margin; the defect that was left was closed by bringing the upper edge to the lower portion, but still there existed a defect in the lower part of the mouth. The submaxillary glands did not appear to be involved. After the wound had healed *x*-ray treatment was applied to the side of the neck three times a week, then twice a week for nearly a year. To-day she talked well, but the paralysis still persisted.

Appendicectomy Followed by Intestinal Obstruction.—Dr. C. A. MCWILLIAMS presented a girl, sixteen years old, whom he first saw September 21, 1903. She then had had appendicitis for three days. A gangrenous appendix was found with about one ounce of pus surrounding it. The wound was drained with a small rubber tube. She did well until the tenth day, when she was taken with vomiting, pain, and collapse. The abdomen was distended and very tender. The distension increased, and at the end of twenty-four hours the vomiting became stercoracious. A second operation was then decided upon and performed. A median incision was made and a volvulus in the small intestine was found attached to the operation scar, that part of the gut above the twist being the size of an arm. One extremity of the cord was loosened and, as her condition was becoming alarming and haste was necessary, the wound was closed with Lembert sutures and the proper dressings quickly applied. The patient did well. Fifteen days later, twenty-six days after the first operation, the same symptoms repeated themselves, and an incision was made and an obstruction was found on the left side caused by a looping of the small intestine. This was at once corrected, and the patient then made an uneventful recovery.

A Case of Rhinoplasty.—Dr. CARL BECK presented this case, which was not at all promising because of the total destruction of the tissues usually employed in this operation. The patient had been operated upon by the French method, then by an Italian method, *i.e.* taking a flap from the arm. Dr. Beck took the flap from the lower lip, as this was an operation that had never been done before so far as his knowledge went. It had the advantage that a mucous membrane was implanted and that the flap need not be larger than was necessary, since, on account of the thickness of the lip, there would occur no shrinkage. The epithelioma had not been treated with the *x*-ray before operation because the tissues so treated were in no condition for operation and would not unite readily. The *x*-ray treatment was used afterward.

Carpal Synostosis after Inflammation as Shown by Röntgen Rays.—Dr. CARL BECK presented an *x*-ray picture of this case. The patient was a woman, thirty-two years old, who had a stiff wrist. The *x*-ray revealed a perfect synostosis between the radius and the carpal bones. It was useless to attempt to sever it, and he did not believe anything but a chisel operation would do.

A Case of Hydrocephalus.—Dr. HENRY L. TAYLOR presented this patient, who had been operated upon eleven months previously. The circumference of the head had increased only two and a half c.m. There was the absence of exophthalmos and nystagmus, and other signs showing that there was really no undue intracranial pressure. It was interesting to note that drainage became most active from two to three months after operation.

Acute Encephalitis.—Dr. BERG reported the case of a boy, an inmate of the Hebrew Orphan Asylum, who tried to slide down the banister after being sent to bed at night, and who fell down two flights of stairs. He was picked up in a condition of profound collapse, with pulse of 52, with left side rigid, and no attempts being made to move. He had a fracture of the neck of the humerus and also a Colles' fracture. On the day following his temperature was 101.6°, pulse from 92 to 122, and respiration from 28 to 36. There were no signs of cerebral compression. The patient was restless, pupils contracted, the left side of face was slightly flattened, and there was a left hemiplegia. The spinal symptoms were negative. The urination and defecation were involuntary. These symptoms seemed to indicate a lesion at the base of the brain, but there was no blood from the middle ear or any cranial nerve palsy. The eyes moved well. It was thought that possibly the injury might have been to the motor area of the cortex, but as there were no symptoms of compression the hemorrhage could not have been extensive, so this possibility was ruled out. Finally the case was diagnosed as one of acute encephalitis. For eleven days the patient was unconscious. Temperature was normal. Consciousness was gradually regained and the hemiplegia gradually disappeared, although he still dragged his right leg. His mental condition was perfect and he soon attended school just as other boys of his age.

Fracture of the Skull.—Dr. BERG reported the case of a boy who, during July of last year, was struck by a brick over the anterior part of the parietal region. Operation was performed, the fracture exposed and a small portion of the bone removed, and the flap replaced. The right arm and leg were partially paralyzed. On September 3 the boy came to Mt. Sinai Hospital and was again operated upon. On exposing the site of fracture there was found a depressed, comminuted and impacted fracture of the parietal bone over the upper part of the left motor area. The depressed fragment was elevated and removed and the wound closed. The dura was not opened as it appeared to be uninjured. The patient still has paralysis of the right leg, the arm having recovered.

ion. He believed the ultimate prognosis was good, e compression did not continue long enough to a permanent lesion.

ula of the Œsophagus.—Dr. Charles N. Dowd ted this case. The patient was an Italian lad, en years old, whose family history was negative. April he noticed a swelling in the right side of the with increasing pain. Poultices were applied t effect. The mass was then incised and a large t of foul, dark pus was discharged. The sinuses larged and curetted, as tuberculosis was suspected. ust the wound was again curetted, and after three weeks, the patient was discharged. He had had d effects of a septic absorption, with temperature from 99° to 103° and 104°, liver very much d, and general condition very bad. In October again operated upon for sternal tuberculosis; ration was intended not to be intrapleural, as the re apparently free from disease. A large incision de over the center of the sternum. Part of the rib was removed, together with the lower margin first and the cartilage of the third. The bone was to be bare and eroded. Under the third rib was sinus, but he could find no tuberculosis. On the ay after operation the discharge was very great. e patient drank water there was noticed a glairy the wound; when the patient was given milk to me of this fluid was found in the wound. Food th was stopped and rectal alimentation resorted e temperature was normal after the operation. neral condition improved, the wound granulating . The congestion of the liver was so great that, time of operation, it reached to the umbilicus. se of the trouble was only conjectured, for there history of cough or spitting and the patient had llowed any foreign body. There was no stricture œsophagus. It was suggested that there might be rticulum whose pressure on the venæ cavæ might t for the condition of the liver.

Surgical Treatment of Internal Hydrocephalus.—ward S. Taylor read this paper. He said that in es examined post mortem there had been found always inflammatory changes in the choroid of the ventricles and ependyma covering the optic i, creating obstruction to the outflow of blood the venæ Galeni, and, therefore, favoring an al amount of secretion into the ventricles. There o a more or less extensive ependymitis, which d absorption and favored increased secretion into ntricles. A constant and important lesion was the ion of the natural outlet for the ventricular fluid. y rare cases one or other foramen of Monro might nd occluded, causing unilateral hydrocephalus. More nly either the aqueduct of Sylvius or the foramen jendie was closed. Only rarely was the central canal cord involved. These various lesions might extend a basilar meningitis, which was secondary to trauma-tubercular, gastrointestinal, nasal, or other infection. rgical aim was largely a mechanical one, to allow the of the retained fluid so as to save the brain from re-damage and to favor its return toward normal tions. He briefly reviewed the surgical attempts had been made for the cure or relief of this condition. thod of drainage to be successful must be internal, be slow, and must be prolonged or permanent. It ed to him as if a small permanent fistula between the icles and the subdural space would most closely able normal conditions, and, in the hope of attaining end, six cases were operated upon by him, under al anæsthesia, as follows:

n osteoplastic flap about two inches in diameter was ned down with its hinge over the base of the mastoid id just above the level of the horizontal lateral sinus. n the lower part of the dura mater thus exposed a semi-circular flap, base downward and about one inch in diameter, was made. Frequently one or two distended veins were encountered beneath the dural flap, and they should not be damaged, for their walls were so friable that the control of hemorrhage was often very difficult. The brain then immediately would protrude through this dural window. A slender aspirating needle was passed through the second temporosphenoidal convolution inward and slightly upward until it entered the ventricle, when the clear fluid spurted out and was collected in a sterile tube for bacteriological examination. Only a very small amount should be allowed to escape in this way. The thickness of the brain-tissue was noted during the insertion of the needle. The drain was then made of No. 2 forty-day chromic catgut. Three loops (six strands) about one inch and three-quarters longer than the thickness of the brain were bound together by a loose spiral of catgut starting at one end and stopping so as to have an inch and a quarter of the loops free. In other words, the drain consisted of a shaft of six strands of catgut a half inch longer than the brain thickness and, spreading from its base, three free loops of gut an inch and a quarter long. Around the shaft of the brain, but not covering its tip, was rolled three layers of Cargile membrane. With a long, narrow-bladed thumb-forceps the tip of the drain was seized and carried into the ventricle along the tract made by the aspirating needle. The tip projected about one-half an inch into the ventricle. The free loops of gut were slipped under the dura between it and the brain surface in different directions, but slightly downward toward the great lymph spaces at the base of the brain. A sheet of Cargile membrane was slipped between the dura and the catgut loops to prevent adhesions. Usually by this time sufficient fluid had escaped from the ventricle so that the brain no longer protruded through the dural window. The dura was sutured with catgut, the bone flap was held by three or four chromic catgut sutures, the deeper soft tissues by catgut, and, finally, the skin with silk. A good sized sterile dressing was applied with some pressure.

The mortality of the operation in the six cases was 50 per cent. In all the cases in which the ventricular fluid was evacuated freely at the time of operation, or during the first twenty-four hours, there was a sharp reaction shown by the temperature, pulse, and general condition of the patient. He cautioned against producing any sudden change in the hydrostatic condition of the brain. The first patient, now twenty months after operation, was considerably improved mentally, but still remained a hopeless physical combination of a feeble body, unable to support or move the enormous head. The second patient, now eleven months after operation, was benefited mentally and physically, and hopes were entertained that he would eventually become a fairly normal child. The third patient lived two months and died of some acute gastro-intestinal disturbance. There was absolutely no change in this patient's condition after operation. The fourth patient died sixty hours after operation. The fifth patient apparently reacted from the operation by the fourth day, then developed an otitis media which drained satisfactorily; finally aneuria developed, and death followed on the eighth day. The sixth patient died suddenly on the sixth day, when he was apparently recovering from the sharp reaction of the first three days. From the above it seemed to him fair to deduce certain fundamental principles for the operative treatment of chronic hydrocephalus: (1) The only feasible method was some form of internal or auto-drainage. (2) Drainage to be successful must be (*a*) permanent or at least prolonged; (*b*) slow, aiming rather to prevent distension of the brain than to cause rapid emptying of the ventricles. Drainage through the aqueduct of Sylvius and foramen of Majendie were naturally slow. (3) Operation must (*a*) be brief, to avoid shock in children; (*b*) involve least necessary traumatism to the brain; (*c*) involve but small escape of ventricular fluid to avoid sudden change in the hydrostatic condition of the brain.

(4) Operation to attain its best results must be done early in the disease before irreparable damage had been done to the brain structures.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held February 15, 1904.

ALEXANDER LAMBERT, M.D., PRESIDENT.

Some X-ray Skiagrams of Incision of the Elbow-joint.—Dr. JOHN H. BRANTH presented these photographs as well as many others showing both normal and abnormal conditions. He spoke of the value of the *x*-ray in epilepsy in his hands, and believed it to be one of the best treatments, making the attacks less severe and increasing the intervals between them.

Dr. WISNER R. TOWNSEND said that much criticism had been made against the employment of the *x*-ray, but he believed it was the operator that should be criticised and not the photographs. In cases of fractures it was absolutely necessary to take *x*-ray pictures from two different planes. The therapeutic use of the *x*-ray was still *sub judice*. He emphasized the proper selection of cases. In the superficial cases, such as lupus, it seemed to act very well; but in the deep processes he was rather pessimistic.

Dr. A. PALMER DUDLEY referred to the great advances that had been made in surgical diagnoses during the past twenty-five years compared to what had been done in such diseases as pneumonia and typhoid fever. He wished to give praise to any man who used any form of the rays that would aid us in reaching internal disease or injury.

The Treatment of Lobar Pneumonia.—Dr. W. GILMAN THOMPSON read this paper. In dealing with this disease he said that all methods had substantially the same aim, to maintain the efficiency of the heart, which was subjected to such a severe and unusual strain. The guiding of the heart's action was, therefore, of paramount importance at the onset, and yet this was the very feature of the treatment which was most difficult to formulate satisfactorily, for it could not be successfully conducted by rule or routine. Each case necessarily presented its own problems and evoked the judgment and skill of the clinician to the utmost. The essential factor throughout was to maintain the proper balance between the heart and vessels, between the intensity of the heart sounds, and the force of its impulse, and the volume and force of the pulse. He said it was a great mistake to overstimulate a heart which, if left to itself, would act well enough alone, and when stimulation had produced a marked improvement in the two great factors of the circulation, the heart force and the pulse tension, it might often temporarily be reduced, or even withheld for some hours to advantage. For these reasons he preferred to make frequent changes in the form as well as the quantity of cardiac drugs employed. It was sometimes stated that heart stimulants should be given to anticipate sudden great weakness, but, excepting in the aged and very debilitated, this emergency was seldom so sudden that it could not be foreseen and met. He had been surprised in following a course of pneumonia in patients having serious organic heart lesions, especially of the mitral valve, to note how tolerant such a heart might be of this infection when not overstimulated by drugs. When the temperature rose above 103 a cold alcohol sponge bath may occasionally be given. If above 105 the cold wet pack should be resorted to. He had abandoned the cold tub bath years ago. He referred to the futility of the many so-called specifics for pneumonia. At the Presbyterian Hospital during the past decade more than 10 per cent. of all cases of pneumonia had resulted in recovery without any medicine whatever, and a large percentage of the rest that terminated favorably were treated symptomatically. He had little belief in the efficacy of the creosote treatment. H not believe that a genuine pneumococcus lobar monia could be aborted when in full career by any s of treatment. Regarding the use of alcohol, he u much less than formerly, and not at all as a routine tice. Many patients did best without it, but in with feeble dicrotic pulses, dry tongues, and profo asthenic he thought it would be indicated but s more than four to six ounces of whiskey or bra twenty-four hours. In the aged and in alcoho should be given. In the majority of cases it wa to withhold it until there were evidences of failing action. If a comprehensive statement was to be regarding the employment of expectorants in pne it would be better said that they were contraind Gastrointestinal disorders he said should receive e attention in both prophylaxis and treatment bec the twofold effect: (1) mechanical, through abd distension or rigidity which embarrasses the resp movements; (2) autotoxic, through absorption ducts of mal-fermentation. The initial dose of should be given and the bowels kept open by effervescing saline laxative. Tympanitis is to be d in pneumonia as in typhoid fever, and was to be s dealt with. He had rarely known a patient to who had a persistent hiccough; it seemed to be central rather than local irritation, and could o relieved by anodynes. The mild cases of delirium best be treated by bromides, codeine, or trions cautioned against the use of morphine. If the d was the outcome of hyperpyrexia the cold we should be employed. With severe alcoholic deli maniacal delirium paraldehyde, hyoscine hydrob and morphine may all have to be tried in turn. of oxygen inhalations was of doubtful utility, said failed to make any impression upon either the or embarrassed respiration in many cases. Yet relieved the subjective dyspnœa, and thus had soothing effect upon the patient, and in some produced an impression upon the objective sy Its use should not be left until the patient wa *tremis*, but should be given early. The import keeping the air about the patient was emphasized. considerable experience with hypodermoclysis in monia he had failed to see any ill effects follow on the contrary, he had saved a few desperate which seemed past every hope of recovery. The dermic injection into the flanks of 1,000, or even of hot (110° F.) normal salt solution (0.6 per cent sometimes enable the patient to rally for an h two when the procedure should be repeated. The injection of salt solution may also prove of great Topical applications to the chest wall should be with the view of promoting the comfort of the pat but it is not at all probable that they have the slig influence upon the course or outcome of the dis Experiments seemed to justify the conclusion tha long as the superficial cutaneous circulation was m tained, the constantly moving blood conveyed either the heat or cold of any external application, the preventing an organ like the lung, which has an inde dent vascular supply, from being influenced. It hardly be maintained that any deepseated effect c into play through external applications of heat or independently of direct transmission of thermal is capable of controlling an inflammatory process o lung. As a rule heat is more soothing than cold, there are many exceptions. Strapping the chest adhesive plaster, although it relieves the pleuritic materially interferes with careful physical examin of the lung. For the above reasons it seems best to ploy no topical applications unless called for by e sive pleuritic pain, and then the choice between and cold should be decided by the patient's com The general hygienic treatment of pneumonia is

stantially like that of typhoid fever. As to diet, with high fever and tongue dried by mouth-breathing, milk is the best food, under more favorable conditions considerable variety may be allowed. The care of the mouth should receive as much attention from the nurse as in typhoid fever, for a foul tongue promotes indigestion, besides making it difficult to swallow. Overzeal in the treatment of pneumonia is more to be criticised than anything else. Overstimulation of the heart, overuse of expectorants, and above all incessant fussing about the patient. Proper intervals of absolute rest of two or even three hours should constitute a definite part of the treatment. An hour's sleep will often do more to save the patient's life than all the medication that he has received throughout the disease. Good nursing and the exercise of constant watchfulness should outweigh polypharmacy and specifics.

In closing he emphasized the following conclusions:

1. The importance of not crowding an overtaxed heart with too much stimulation, and especially of basing the selection of the proper variety of cardiac stimulant upon the existing balance between the conditions of vascular tone and the effort the heart is already making.

2. The uselessness of the so-called specifics for pneumonia, and, as a rule, of expectorants.

3. The importance of the prevention of indigestion, and particularly of tympanites.

4. The great value of hypodermoclysis in certain cases.

5. The uselessness of topical applications, excepting for the purpose of relieving pleuritic pain.

6. The necessity of prescribing proper intervals of rest in which the patient is free from incessant efforts at medication.

Dr. GEORGE L. PEABODY said that his experience had been somewhat different from Dr. Thompson's, and he believed that the essence of the attitude regarding this grave disease was intelligent symptomatic treatment. With regard to the cold tub-baths, every winter he met with cases of violent, uncontrollable delirium, in which the cold-bath acted very well as a sedative. Almost all of these cases had produced upon them a sedative effect, and he had no doubt but that in a certain per cent. of these cases he had saved life when they appeared to be doomed to die, as the result of the exhaustion from the constant delirium. He then narrated a few cases to illustrate that fact. Regarding the use of hypnotics, he said he was as strongly opposed to them as was Dr. Thompson, even if pain was present. He thought an application of heat to be quite typical, and if this failed to relieve then one-sixth of a grain of morphine, administered subcutaneously and repeated once during the night if necessary, would be productive of good. There was a confusion of ideas regarding the employment of morphine in the treatment of pneumonia. It was stated that morphine depressed the function of respiration, and on that account some dreaded the use of it in any disease with such a disordered function. Morphine did not effect the peripheral, but only the central respiratory act, and, in pneumonia, the central respiratory function was not at fault. With regard to other hypnotics, he did not use sulfonal or trional at all because they were too long in action; he preferred paraldehyde or amylene hydrate, even though they were quite nauseating. These agents may be given by rectum. Paraldehyde might be given in peptonized milk and in doses of one or two drachms. Amylene hydrate may be given in doses of one to two drachms in water. In using these drugs he advised that much of the vehicle should be used. He had no faith in the use of antiseptic inhalations in pneumonia. He was surprised that up to this time no brilliant claims could be made regarding any specific treatment of pneumonia. For some time past he had been treating cases of pneumonia in a routine fashion with one of the salicylates. Of late he had been using sodium salicylate and aspirin, because the latter was better borne by the stomach. There was needed a large number of cases before he could quote statistics in favor of any treatment, and he was not prepared at present to give any mortality rates, because of the small number of cases he had had to deal with. He had treated between sixty and seventy consecutive cases of pneumonia with the salicylates as only a part of the treatment. During the past winter he had treated thirty-eight cases this way. That this treatment had some influence upon the disease was proven by the fact that defervescence took place commonly by lysis; in 32 per cent. of them by lysis. This showed him that the salicylates had some influence upon the disease. The patients seemed to bear the disease with less disturbance. A certain number of the cases certainly did better upon this treatment than others. He believed that we should be on the lookout constantly for some specific treatment for this dread disease. Regarding the abortive treatment, he was very skeptical. Years ago the late Dr. Leeming believed in the abortive treatment by large doses of calomel, but Dr. Peabody had not seen any good effect by it. Hiccough was a bad symptom. In severe and persistent hiccough with high arterial tension he had given inhalations of amyl nitrite with good results when pushed to their physiological effects. Oxygen was an agent he did not believe one was much justified in giving, except in the early part of the disease before signs of cyanosis developed; then he believed it to be a valuable remedy, and often would turn the scale in the patient's favor. He deprecated the plan of placing it in the room just prior to the patient's death. As a local application he liked the electric warm pad, by means of which he could keep up continuously a regular temperature for some time.

Dr. L. A. CONNER spoke of his experience in the Hudson Street Hospital. In general, he coincided with all that Dr. Thompson had said. The treatment employed there was entirely symptomatic. Unless stimulants were really demanded they received none. The diet was usually milk, but the patients were required to drink abundantly of water. Regarding the use of alcohol, not one-quarter as much was used now as three or four years ago, and without less satisfactory results. During the past two years all patients had been placed upon carbonate of creosote in 10 to 15-grain doses every three hours, and he hoped eventually to be able to present some statistics regarding the effect of this agent upon the outcome of the disease. So far they had had two hundred cases; one-half of them received carbonate of creosote, and the other half didn't. The cases were not yet tabulated. He emphasized the importance of watching the condition of the abdomen in this disease, especially the tympanitis. In pneumonia this was more serious than in typhoid fever. Great difficulty was experienced in treating the tympanitis, and turpentine stupes applied to the abdomen frequently and colon irrigations of alternating heat and cold seemed to give the best results. Pulmonary œdema was best treated by dry cupping, but, to be effective, this must be done frequently.

Dr. CHARLES E. QUIMBY said that Fitz of Boston had gone over very carefully the statistics regarding this disease covering a period of forty years, and he had found that the mortality varied but very little. Topical applications he believed to be beneficial; he was thoroughly convinced that keeping a uniform temperature to the surface had a good effect upon the circulation of the lungs. The dry cough could be relieved in many cases by dry friction. He said it was very desirable to get a uniform temperature over the body. He thought it a good plan to have the temperature of the room above eighty degrees at all times, and full of moisture. Because the chlorides were diminished in the urine in pneumonia, he gave sodium chloride from the beginning of the disease.

Dr. MORRIS MANGES said that certain statistics were reported from the Massachusetts General Hospital, which covered a period of nearly one hundred years, and not forty years as quoted; the average mortality ranged between 10 and 11 per cent. In these statistics were excluded those cases that occurred in the very young and very old and, therefore, were of limited value, especially in the consideration of the pneumonias which have occurred since 1890 when grippe became prevalent. He then referred to Wells statistics which had been amplified by Osler; here were taken all cases, and the average mortality was 20 per cent. These latter statistics were taken from all over the United States, and were not 1,000 but 255,000; these were the statistics which he believed should be consulted when considering the mortality of pneumonia. He thought that the disease to-day was different from what it was a few years ago. He believed that the routine examination of the abdomen was of greater importance than the routine examination of the lungs. The paralytic distension of the bowels was not alone due to the intestinal contents, but also to a septic process. Those cases in which there was no relief from the tympany were those cases beyond the reach of local treatment. He warned against the use of even mild cathartics in cases of abdominal distension, especially when of septic character. With regard to dry cupping, those who have used it will continue to use it because of its good effects. Venesection in some subjects he believed to be valuable, especially in sthenic cases. In cases of catarrhal pneumonia associated with grippe he believed that guaiacol was an effective agent. Salicylate of sodium seemed to act well, especially in children. He said he was afraid of morphine in cases of pneumonia. Tentatively he had tried heroin, but was not satisfied with the results. He emphasized the importance of the patients getting plenty of sleep both by day as well as by night.

Dr. EDWARD W. LEE emphasized the importance of hypodermoclysis, or the injections of large quantities of water in those cases of pneumonia, especially those following surgical operations.

Dr. ALEXANDER LAMBERT said that his attention had been drawn to the use of ergot as an equalizer of the circulation, constricting the dilated vessels, and he had used it in the alcoholic and other pneumonias. He had also used it in the tympanitis distension which occurred in both children and adults. It seemed to act well in œdema of the lungs. In his hands this agent had given satisfactory results when used with dry cupping in œdema of the lungs, and was more satisfactory than anything else he had used for this condition. It had a marked effect in getting rid of the congestion.

Dr. THOMPSON closed the discussion, and said that pneumonia was so often noticed after surgical cases because of the lowered vitality caused by the operation. The pneumococcus was present in one out of every five normal mouths, so the opportunity for the disease to develop was always present under certain circumstances. He said he preferred to have the patient's body accessible and not clothed with such garments as proposed. He said he was surprised to hear what was said regarding the respiratory difficulty being seated in the lungs; the trouble was from the action of the toxic material contained in the blood which acted upon the respiratory center in the medulla. This was proven by the fact that when defervescence occurred the cyanosis cleared up, etc., when the lungs were not entirely resolved. He said the dyspnœa and respiratory symptoms were distinctly of central origin, and was due to the poison contained within the blood. Therefore, morphine when employed in those cases in which the cerebral centers were overwhelmed with the poison was injurious. To use it as a hypnotic he believed made matters much worse.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting, held February 23, Dr. C. D. Camp exhibited a case of "Erythromelalgia" in a man, who fifteen years previously had had the right foot partially frozen. The member had now for some time been red and exquisitely painful in the dependent position, becoming however, of a deathly pallid hue when elevated, and the blood was drained from it. The general health had suffered greatly in consequence of the intensity of the pain, and the advisability of operative treatment, such as nerve-stretching or nerve-section, was being considered. Dr. Camp exhibited also a case of "Paralytic Chorea" in a boy who, when he first came under observation, presented marked loss of power in the right upper extremity, and less in the lower extremity, with comparatively slight choreic movements. The latter, however, became more conspicuous as the former, under treatment with Fowler's solution of potassium arsenite, moderated. For a time it was thought that the patient might have some lesion of the brachial plexus, the paresis was so marked. There was no history of rheumatism, and there was no heart-lesion.

Dr. D. J. McCarthy exhibited two cases of "Tuberculous Neuritis." He stated that it is not altogether rare to encounter neuritis, especially in the distribution of the anterior tibial nerve, in the terminal stage of pulmonary tuberculosis, but in the two cases presented the patients had exhibited improvement in the pulmonary lesions, and in the general condition. The affected muscles exhibited weakness and wasting, and the reflexes were enfeebled, as contrasted with exaggeration of the reflexes observed in the absence of neuritis. Under the latter circumstances a posterior tibial reflex can often be elicited by irritation of the plantar aspect of the arch of the foot, and an anterior tibial reflex by a blow below, and to the outer side of the tubercle of the tibia. These reflexes cannot, as a rule, be obtained in healthy individuals. Examination of nerves that have exhibited symptoms of inflammation has disclosed the existence of characteristic histological lesions.

Drs. C. W. Burr and B. F. Stahl reported a case of "Bulbar Myasthenia" with autopsy. There were present during symptoms of paralysis of bulbar nerves, while after death an encapsulated abscess of the persistent thymus gland, together with lymphomatous infiltration of muscles, was found. Similar conditions have been observed in other instances, so that a question arises as to the possible causal relation between the persistence of the thymus gland and its involvement in disease and the bulbar symptoms.

Dr. W. G. Spiller and T. H. Weisenburg reported three cases of "Paraplegia Dolorosa" with necropsy. In one of these cases malignant disease of the vertebræ was found, in another an abscess of the vertebral column, and in the third tuberculosis of the vertebræ. Dr. Wm. C. Pickett read a paper entitled "Mental Symptoms Associated with Pernicious Anæmia." He pointed out that Addison in his early description of the disease had noted certain mental peculiarities. In some cases symptoms of involvement of the spinal cord are present, while in others there is a more or less characteristic form of psychosis, with illusions and hallucinations, disappearing with improvement in the state of the blood.

CINCINNATI ACADEMY OF MEDICINE.

At a regular meeting of the Academy of Medicine in Cincinnati February 22, Dr. Francis Dowling presented a case of "Penetrating Wound of the Eyeball." The patient, a laborer of about forty years, had been struck in the eye about Christmas time by a piece of flying iron. He was seen first by Dr. Dowling one week later. An incised wound at the sclerocorneal margin was found, involving about two-fifths of the circumference with protrusion of the iris. The eye was found to have some

vision, so after telling the patient the dangers it was decided to try to save the eye. At present the eye has about three-sevenths vision, and has given no further trouble. Dr. Eckman of Covington, Ky., presented a case of "Double Varicocele Operation" in a boy of eighteen years. On the right side a short inguinal incision had been used and the operation, resecting of two inches of distended veins with closure of the wound had occupied six minutes. On the left side the old scrotal operation had been done, and the operation had lasted much longer. He wished to illustrate the ease and quickness with which the inguinal operation could be done.

Dr. B. F. Lyle reported a case of "Rapidly Consecutive Infections." The patient was a young boy from Kentucky, who was first seen with a chickenpox eruption, the whole family of six broke out with the same disease. The boy then began to suffer with malaise and aching pains, and was sent to the hospital, where after four days an eruption of smallpox developed, and he was sent to the pest-house. After his recovery from smallpox he broke out with the rash of scarlet fever, and is at this time in the middle of the attack. These three diseases all attacked this child within one month. Dr. Byron Stanton spoke of the paper by Dr. R. W. Marsden in the *British Medical Journal* of December 26, "The Stage of Invasion of Measles," and said he had two cases to add to those reported. He reported the case of a child which was exposed to measles, and on the eighth day had rise of temperature, photophobia, and coryza, the diagnosis of measles was made and the appearance of the rash confidently expected on the fourth day, but this failed to appear until the sixth day, fourteen days after exposure. The second case was not known to have been exposed but developed the prodromal symptoms of a typical case of measles. The rash in this case also did not appear until the sixth day. He said that it was his belief that when the prodromes came unusually soon the eruption was usually delayed to make the whole period from exposure to eruption about fourteen days, and that the earlier the prodromes appeared the longer would be the invasion.

Dr. Edward H. Shields reported a case of "Gumma of the Liver." The patient was a man of thirty-four years, married, the father of one healthy child. He had had syphilis eight years before and twelve years ago had had a sarcoma removed from the right breast with no recurrence. For a little over two years the patient had been under treatment of another physician for irregular attacks of fever with colicky pains. Four months before seen by Dr. Shields he had developed irregular attacks of high fever with chills and sweats, pain at times in region of the cæcum, meteorism, obstinate constipation, loss of appetite, and pronounced anæmia. Physical examination gave negative results, except for slight enlargement of the liver. A diagnosis was made of chronic colitis and appendicitis, with possible affection of the gall-passages. An operation was performed, and the appendix was found adherent to the cæcum, and containing concretions and bloody mucus. The gall-passages were normal, but in the lobus spigelius was felt a hard inelastic nodule the size of an English walnut surrounded by smaller nodules of similar character. The liver elsewhere was normal. The post-operative diagnosis of the liver condition was recurrence of the previous sarcoma or syphilitic gumma. Recovery from the operation was uneventful, but colicky pains recurred, and potassium iodide five drops of a saturated solution three times a day had no effect. When seen by Dr. Shields the patient had lost fifty-five pounds, and was anæmic, suffered severe pain in right hypochondrium, which often radiated to right shoulder and back, and also colicky pain in umbilical and left inguinal regions. The temperature ranged from 101° to 104°; the pulse from 100 to 120, and the respiration from 18 to 26. The liver was somewhat tender on deep palpation, no enlargement could be made out. The diagnosis of gummata of the liver was made, and potassium iodide was quickly pushed to tolerance (at this time seventy drops three times a day), and continued for six months. At end of one month patient had gained thirteen pounds, and at the end of one year weighed one hundred and eighty pounds, an increase of fifty-eight pounds.

Chicago Medical Society.

At a meeting recently held, Dr. Theodore Tieken read a paper on "Cryoscopy." He reviewed in detail the evolution of cryoscopy and the literature up to the present time. He summed up the conclusions of other workers along similar lines and compared the results with those he obtained. During the past eighteen months he had examined the blood and urine in 330 cases, making in all over 500 estimations of the freezing points. He found that the results obtained by Koranyi, Kummel, Kasper, and Richter, Rumpel, Tinker, and others were correct, and that the slight differences might be accounted for by errors in technique. He used the Beckman apparatus for both the blood and urine, and gave the normal freezing point of blood at 0.56° C. below zero, as found by previous workers. The urine, as collected for a usual twenty-four hour specimen, freezes at 1.46° C. in the average normal individual, but the normal limits vary from—.98 to 2.56°. He found that the freezing point of the mixed urine did not give so much information as to the functional activity of the kidneys and that a catheterized specimen from each kidney was necessary to be of help to us. The freezing point of the blood was nearly constant—(0.56) and the normal variations were much less than in the urine—.55-.57° C being usually given, but we must not be misled by the variations occurring in the freezing point of this fluid, as it, too, was subject to outside influences. He thought that cryoscopy would be of value in many cases, especially when used in connection with the other methods of diagnosis, as ureteral catheterization, the phloridzin test, and careful chemical and microscopical examination.

Dr. Louis E. Schmidt read a paper on "The Use of the Cystoscope in Catheterizing the Ureters as a Means of Diagnosis in Surgical Diseases of the Kidneys." He stated that examination of the bladder, catheterization of the ureters, examinations of the functional activity of the kidneys by examining separately the collected urines, especially with the aid of cryoscopy and radiography gave almost certain information by which one might be safely guided in this field of operative work. As to cystoscopy, every diagnostician agreed as to its true value in this work. With the help of the cystoscope the presence of only one or of two ureteral openings could be determined, and whether or not clear, turbid, blood-tinged, or colored urine was being secreted from one or both sides. The appearance of the ureteral orifices, tear after the passage of stone, as reported by Halban, inflammatory signs of the mucosa, or tuberculous processes, or papillomatous growths about the urethral orifice might designate descending processes. After inhibition per mouth of methylene blue, the urine became tinged green in from thirteen to fifteen minutes in the case of a normally secreting kidney. The greater the amount of parenchyma destroyed, the longer the time which elapsed previous to the appearance of the tinged urine. Voelcher and Joseph had injected sixteen centigrams of indigo carmine into the gluteal muscles. It began to make its appearance in the urine in from fifteen to thirty minutes. It had the advantage of being excreted solely by the kidneys, and was harmless. The same authors gave individuals iodide of potassium, and filled the bladder with a solution of peroxide of hydrogen containing starch. As soon as the iodide of potassium was being excreted, the urinary whirl became of a bluish

color. When catheterization of the ureters or segregation was impossible or undesirable, when the ureteral openings could not be seen, it was possible by means of a cystoscopic examination to make some deductions as to the functional activity of the kidneys when considering the foregoing points. Besides, it was possible to ascertain approximately the functional activity by watching the frequency and force of each contraction, the quantity of urine which was expelled at each contraction of the ureter, and also some idea as to the ascent or descent of the whirl when the bladder was filled with fluids of varying specific gravities. Reference was made to the use of the different segregators. After considering the advantages and disadvantages of the various methods, the author said that ureteral catheterization was constantly becoming more popular. While he did not care to make a comparison of segregation and catheterization of the ureters, he believed there were but few, if any, authentic cases of infection of the ureter following catheterization. There could be no question in the minds of those who had followed the subject, and who had had practical experience, that the establishment of the functional activity by the examination of the urine gained by ureteral catheterization was the most important achievement in renal surgery. In addition, certain information which was of importance in every case was derived by ureteral catheterization, which any one of the segregators and cystoscopy alone could not give. It was a method of diagnosis which could give valuable information in both ureteral and renal affections. When a stone in the ureter had been diagnosed, and the skiagraph showed it to be correct, Kolischer, Caspar, Hausmann, and the author had been able to inject sterilized liquid vaselin, which had been sufficient to cause contractions and to loosen the stone and cause the spontaneous expulsion of it into the bladder, and then subsequently it was passed naturally per urethram. It was not to be forgotten that when a catheter or bougie was in place, it could be used as a guide in ureterotomy, and also to locate and prevent traumatism of the ureter whenever bound down by tumors or inflammatory processes. Whenever one was performing a plastic or other operation, on the pelvis or kidneys, a bougie in place might serve as a guide. For draining the pelvis in cases of pyelitis and flushing it out and treating it, nitrate of silver, or other solutions had long been in vogue, and in some cases with beneficial results.

Medical Society of City Hospital Alumni of St. Louis.

At a stated meeting, held on February 18, Dr. J. Mather Pfeifferberger reported a case of "Ligation of the Common Carotid Artery." The patient had been stabbed on the left side of the neck, about half an inch below the angle of the jaw. The wound was enlarged and extended down to the anterior of the sternocleidomastoid muscle, the compression removed, and the site of injury to the artery located near the bifurcation. The vessel was dissected out from its sheath, an aneurysm needle with ligature attached was passed under the artery, and the vessel drawn up and ligated in two places. This controlled all hemorrhage. Before reaching the hospital the patient had lost a great deal of blood, and two injections of normal saline solution 850 c.c. each were given. Three hours after operation the patient vomited, and an hour later there was profuse sweating on the right side of face and body, and he was unable to move that side of the body with the exception of the fingers. The tongue protruded toward the left side and could not be moved to the right side. There was a slight drooping of the angle of the jaw to the left side. Pupils responded to light and accommodation. There was some difficulty in speech and swallowing. On the next day the pulse was 126, respiration 24, temperature 99° F. When asked to move fingers on the paralyzed side patient could do so, but not without moving the fingers on the other hand also. On the fifth day the pulse was 90, temperature 99.4°, respiration 24. Could move fingers on paralyzed side when the other hand was closed. After this the pulse and temperature gradually dropped to normal. On the eighth day he could put his hand to his mouth and raise arm from his chest, but could not move the rest of the right side. Impediment in speech was still present. On the fourteenth day patient was taken home.

Analyzing the symptoms following the ligation of the artery Dr. Pfeiffenberger thought the disturbance in speech and swallowing was probably due to injury of the descending hypoglossis, which was probably severed at the time of injury to the artery, but it might have been due to a central lesion. The partial hemiplegia could be explained by the condition of anæmia produced by the sudden cutting off of the blood supply to the left side of the brain. Although the patient lived and improved, the essayist since investigating the results of ligation of the common carotid, thought more conservative surgery might be advisable, but the condition of the patient in this case demanded immediate attention, and the course pursued seemed to be the only one open.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

New Instruments.

TABLE DESIGNED FOR PHYSICIANS' ICE USE, AND PARTICULARLY ADAPT- FOR PELVIC WORK.

By H. J. BOLDT, M.D.,
NEW YORK.

sence of a suitable office table of modern admitting of easy and rapid adjustment to he various requirements for ation by the surgeon or the logist has prompted me, with istance of The Kny-Scheerer New York City, to design a e table which answers every ment.

table (Fig. 1) is constructed of nished in white enamel, and it of easy adjustment to place tient in any position without to the patient. It is easily and

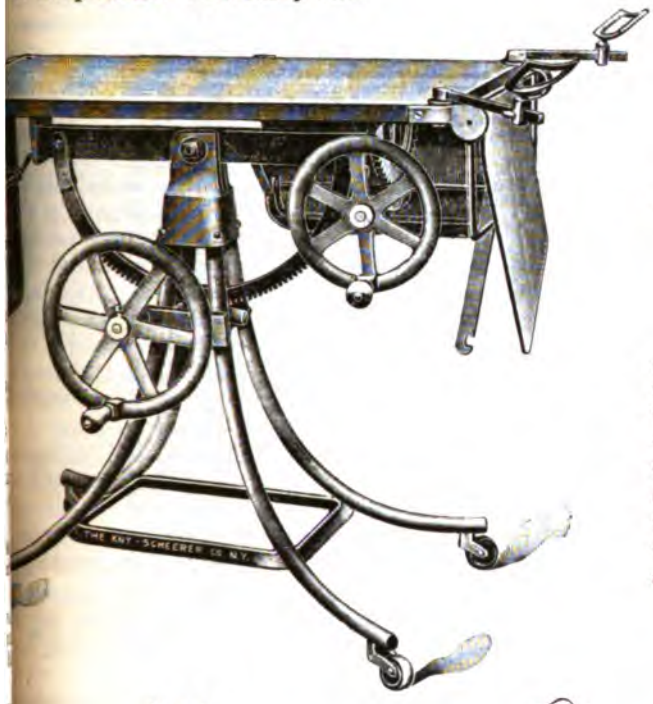

Fig. 3.

y depressed at either head end or foot tilted laterally to the right or left by g the wheels to the side. It is parti- y adapted to the knee-chest position for amination of the bladder, and catheteri- of the ureters if used with the side- shoulder support and body strap as shown re 2. The table is equipped with adjust- nickel-plated heel stirrups which can be ted to any desirable angle. It has an table plate to facilitate the Sims position tly as shown in figure 3.

e table is strongly constructed, and when e as an operating table, the side plate e placed horizontally to hold an instru- tray or a hand basin. The dimensions e table top are 22 inches wide, 36 inches The total length including the Sims and head end when raised is 66 inches. height is 31½ inches. The side shelf for nees is 10 inches wide by 18 inches long. preciation of the popular success of my er efforts in designing a general operating with the assistance of the same firm, warrants me in submitting this new model of office table in the anticipation that the profession may find it of assistance.

30 East Sixty-first Street.

Nauheim Treatment.—Thorne gives, in the *Lancet*, a classification of cases of heart disease based on their suitability or not for the Nauheim treatment. The cases which will be either cured or greatly benefited are: dilatation of the heart from influenza, typhoid fever,

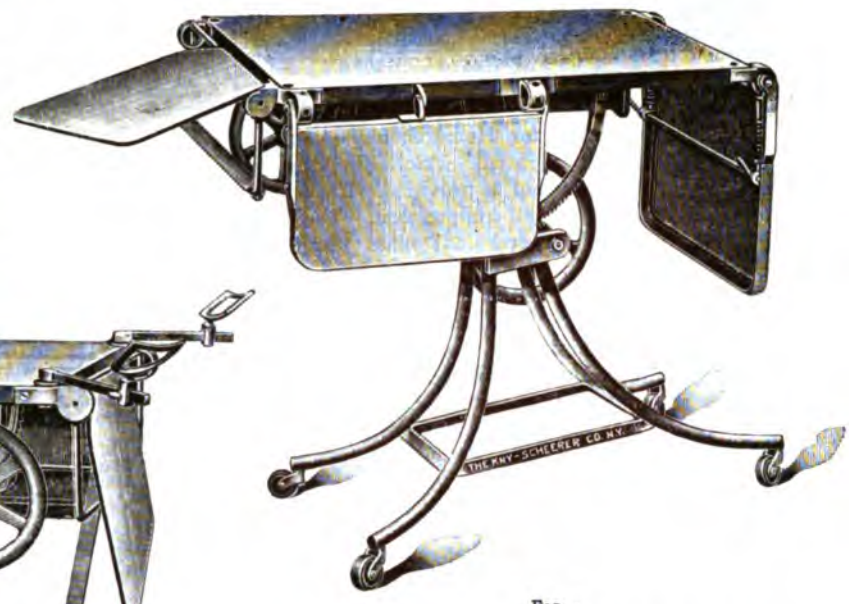

Fig. 1

malaria, excessive smoking, and due to the raised arterial tension of the gouty diathesis. The cases which will be benefited are those of valvular disease with commencing cardiac failure. Unsuitable cases are: habitually heavy drinkers, cases of syphilitic disease of the heart, those with marked degeneration of the vessel walls, those with typical aortic regurgitation, and very old people.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 5, 1904:

	Cases.	Deaths.
Measles	1435	30
Diphtheria and croup	408	41
Scarlet fever	551	27
Smallpox	1	...
Varicella	136	...
Tuberculosis	405	188
Typhoid fever	27	8
Cerebrospinal meningitis	...	11

A New Operation for Hemorrhoids.—Landström employs a modified angiotribe which has long thin jaws, with rounded edges, and is provided with a heavy screw for producing powerful compression. The sphincter is dilated and the hemorrhoidal mass seized as in the clamp and cautery operation. The jaws of the instrument are then tightened as forcibly as possible by means of the screw and the tumor is cut away. Owing to the compression of the tissues, no cauterization is necessary and the clamp may be removed at once. The pedicle is as thin as paper and does not bleed from its edge or base. The clamp may be applied to several points of the circumference without any danger of hemorrhage. The operation is more rapid and followed by less pain than by any of the other methods.—*Centralblatt für Chirurgie*, 1903, No. 47.

The Röntgen Therapeutic Reaction.—Guido Holzknecht says that the remarkable peculiarity of Röntgen dermatitis is its long period of "latency." It is known that one to four weeks intervene from the day of exposure to the date of visible reaction, and that the "latency" time is longer as the absorbed mass of light is less. Applied to the normal skin of the face (hypertrichosis), in order to secure a reaction of the first degree (erythema, depilation), 3.5 H (H=the author's Röntgen light unit) was used. An hour later the whole area not covered with lead sheeting appeared light reddish, burning, and hyperæsthetic. The condition reached its climax in two hours, the redness alone remaining, growing less daily until the eleventh day. The erythema increased, the color becoming a deep blue-red. On the fourteenth day the hairs were loose and could be removed without pain. The true Röntgen reaction appeared, therefore, on the eleventh day, after the period of latency, and we must separate the unusual prior appearance of the light, superficial inflammation of the "rayed skin," which is termed "prereaction," from the true Röntgen reaction. The further course of the reaction differed materially from the common reaction. The dose (3.5 H) led one to expect the beginning of a reaction of the first degree, and a period of convalescence in about two weeks. This would have been expected after a period of latency of eleven days, but a reaction of the second degree took place. On the twentieth day vesicles appeared, and soon afterward an excoriation of the whole surface resulted. The usual progress would be a period of convalescence of four to six weeks, but after two weeks the whole exposed surface was covered with skin. The prereaction in the superficial layers of the skin upon the following typical reaction no doubt intensified the inflammation. No similar change took place in the deeper tissues, allowing quick recovery. We see, therefore, that the prereaction complicated the course of the Röntgen reaction and of the convalescence. It produced superficially an intense reaction. The prereaction is not constant; it is no doubt influenced by peculiar conditions. It was found that the tube was coated black in all the cases of prereaction. The prereaction can be avoided by discarding every tube as soon as it causes a prereaction for the first time.—*Archiv für Dermatologie.*

Surgical Treatment of Exophthalmic Goiter.—[illegible] sums up his conclusions as follows: (1) Exoph[thalmic] goiter is successfully treated by operation in [the] majority of cases (about 75 per cent.). (2) T[he] rate of the operation is very high, but in the [hands] skilled surgeons is reduced to 6.3 per cent. (Koc[her]) in cases operated upon early as low as 2.4 per cent. (3) The principal dangers from the operation [are] from the anæsthetic, hemorrhage, and post[operative] thyroidism—dangers which may be partially [avoided] the use of local anæsthesia, by skilled manipu[lation] proper preparation of the patient and by early [operation] (4) The question, whether or not operations on t[he] are preferable to those on the sympathetic ner[ves] be decided until we have fuller statistics of t[he] of sympathectomies at our disposal.—*Detroit Journal.*

Health Report.—The following cases of [smallpox,] yellow fever, cholera, and plague have been [reported] to the Surgeon-General, U. S. Marine Hospital [Service] during the week ended March 5, 1904:

W TREATMENT FOR FRACTURE OF THE NECK OF THE FEMUR.

By ROYAL WHITMAN, M.D.,
NEW YORK.

uld appear that my contention, that fracture e neck of the femur is not uncommon in early s now generally admitted. Further experience onvinced me also that this fracture is far more on in young and vigorous adults than statistics te. In my last communication on the subject *ls of Surgery*, November, 1902) I cited five seen in one year in patients from twenty-eight y-five years of age, in not one of which had the osis been made. From the histories of these f similar cases, it would appear that in middle s is almost always the case in childhood, the re is often incomplete, and is therefore unrecog-

But that an injury, presenting such obvious al signs, is so often mistaken for contusion, after the disability has persisted for months, e explained only by ignorance of the details ysical examination and of the characteristic toms of distortion of the neck of the femur.

is the number of these patients, crippled in ous life, who have sought treatment months or after the injury, not merely for functional dis- y but for persistent discomfort and pain, that timulated my interest in the question of pre- on by more effective treatment.

the outset one encounters the traditional belief, this particular fracture usually occurs in the , the fat, and the aged. Or, more particularly, the age of the patient in most instances makes pplication of effective treatment impracticable. belief is not, however, supported by statistics. in Hamilton's cases treated at Bellevue Hos- which are manifestly not representative, it may ted that but 37 per cent. were more than sixty of age, and that 40 per cent. were fifty or less. the general belief, also, that the mortality after injury is high, yet, in a series of 241 cases treated ree consecutive years at Bellevue Hospital, were but three deaths; one from pneumonia in twenty-four hours after admission, and two alcoholism and nephritis. In seventy-one treated at the New York and St. Vincent's pitals during the same period, there was but one h. (Bissell, *Philadelphia Medical Journal*, May 1903.)

aditional teaching has more influence for ill than d at first appear. For example, if the elbow of ung person is injured, fracture is suspected be- it is known that fracture is common in this tion. If the same person sustains an injury at hip, it is classed as a contusion because fractures supposed to be so unusual in this locality. Thus favorable opportunity for treatment is lost in very cases in which it should be most efficacious. It may be assumed, also, that the supposed grav- of the accident prevents, in many instances, the plication of local treatment in the older class, and any event this treatment is usually perfunctory and symbolic in character. In fact, the patient, of whatever age or condition, is practically condemned to greater or lesser disability when the diagnosis is made. Bissell, in the article already referred to, presents the patient's prospects as follows:

"If he escapes with his life he has to be contented with loss of function, loss of symmetry and equipoise, and is often obliged to go about permanently crippled."

Scudder investigated sixteen cases that had been treated at the Massachusetts General Hospital. Seven of these were between forty and fifty years of age and but three were more than sixty. "In but two instances could the limb be said to be functionally useful."

Hyde (*Medical Gazette*, April 17, 1880) examined twenty patients after discharge from Bellevue Hospital. He states that but one of these was free from pain. In the majority of cases the limb was flexed, and support was necessary to enable the patient to walk. Several of the patients were bedridden.

It is interesting to note that the treatment of fractures in general is skilled treatment in the inverse ratio to the severity of the injury. For, while ambulatory cases in the class in which fractures are most common are treated by surgeons whose experience has enabled them to become expert, the bedridden class comes under the prentice hands of house officers, whose treatment must of necessity conform to established methods.

Whether the statistics quoted are representative or not, it will be generally admitted that the results of treatment of fracture of the neck of the femur, as compared with those ordinarily attained in other situations, in the same class of patients, are most unsatisfactory. The reasons for this will be apparent on consideration of the nature of the injury and of the means that are employed to remedy it.

Although the old distinction between intra- and extracapsular fracture has lost much of its significance, yet the situation of the fracture is of great importance. If it be at the junction of the neck with the shaft it should be comparatively easy to secure union because of the large area of the fragments and because the fracture is often incomplete, as in the younger class of patients.

If it be of the small part of the neck, apposition and retention will be more difficult, and union of course unlikely if the primary shortening of the limb is not overcome. If the head of the femur be involved, as in epiphyseal fracture or separation in young subjects, the irregularity at the articulating surfaces will inevitably cause interference with function, even, it may be, to the degree of practical ankylosis.

The typical treatment for complete fracture of the neck of the femur is the long lateral T splint to which the limb and body are bandaged, supplemented by the traction force of a weight of from five to twenty pounds attached to the limb. The splint is applied to prevent movement at the seat of injury, and the traction is supposed to resist muscular spasm and to overcome eventually the shortening caused by the upward displacement. It should be apparent, how-

ever, that the weight acting against the friction of the bed, upon a limb bandaged to a lateral splint, can have but slight influence on the deformity, as is demonstrated by the shortening that is present in most instances when the apparatus is removed. It is evident, also, that if the fracture be of the small part of the neck, the persistence of an inch or more of shortening practically precludes union, because in such cases the fragments are not in apposition. Even if this apposition were attained, there must be, in the absence of antero-posterior support, a degree of mobility, as the patient is necessarily moved from time

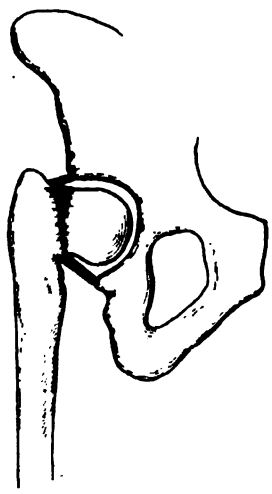

FIG. 1. Incomplete fracture, of the type often found in childhood illustrating the mechanical limitation of abduction.

to time, that would interfere seriously with union. In some instances sand-bags are used in place of the splint, or traction alone is employed, or the limb is suspended in a Hodgen apparatus, but the principle is essentially the same.

In impaction or incomplete fracture, the neck is forced downward and usually backward, or in some instances is driven into the shaft of the femur, a deformity that might be described as traumatic coxa vara. One is taught that no attempt should be made to remedy the distortion for fear of non-union. Yet this surely condemns the patient to disability,

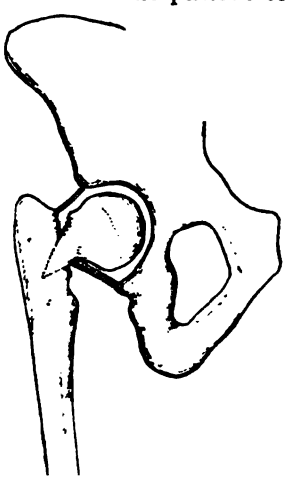

FIG. 2. A form of impacted fracture.

not because the limb is rotated outward and somewhat shortened and because the patient limps, but because of direct interference with the function of the joint. For, with the lowering of the femoral neck, there is corresponding limitation of abduction of the limb, a limitation that is usually progressive and that leads, in many instances, to persistent flexion and adduction. This distortion is induced primarily by the deformity; it is favored by the attitude assumed by the patient during the stage of weakness and repair, and it is confirmed by the accommodative shortening of the adductor muscles.

In most cases of this character there is persiste discomfort and pain whenever the contracted m cles are suddenly stretched by an unguarded st It is probable, also, that the greater strain to wh the depressed neck is subjected may, as in youn subjects, lead to further distortion and induce nutritive changes of the osteoarthritic character p sented by museum specimens.

As the object of treatment is the restoration normal function, the present treatment of fract of the neck of the femur is defective in principle in practice, since no attempt is made to restore normal contour when the fracture is incomplete,

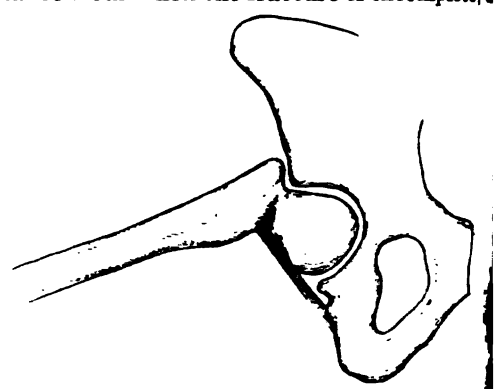

FIG. 3. The deformity reduced by leverage against the upp of the acetabulum.

when it is complete the means taken to secure are feeble and perfunctory.

It is far easier to point out defects than to s a practicable remedy, and as that to be presen the outcome of actual experience it may be of est to sketch briefly the process by which it wa it were, evolved.

When the first case of fracture of the neck of femur in childhood came under my observation fo teen years ago, it was looked upon as a surgical c osity and of particular interest in the differe diagnosis of tuberculous disease of the hip-joint which it had been mistaken. The obvious t ment was to relieve the symptoms by appropr

support; for at that time, before the now fa subject of coxa vara had been discussed, the dep ence of normal function upon normal form wa appreciated. The later examination of this similar cases showed that increasing rather tha creasing disability was the rule; in other word the traumatic as well as in the simple forms of vara slight depression of the neck of the femu duced greater depression. The first conclusion that one should wait until the process had checked by the resistance of the depressed bone then remedy the adduction and rotation of the

simple linear osteotomy of the shaft of the femur. The next step in treatment, both for simple and matic cases, was in the direction of prevention the progressive deformity. At first the only cticable means seemed to be the application of race, but this treatment, burdensome, tedious,

e from the base of the trochanter seemed to manifest advantages over simple osteotomy of haft, in which there was a possibility of over- g of the fragments, or direct operation on the with the possibility of non-union and of in- n.

he first case treated by this method it was very lt to bring the opposing surfaces of the wedge ontact, but later this difficulty was overcome ducting the thigh until the trochanter and neck into contact with the upper border of the ulum, then further abduction of the limb, g the thin cortical substance on the inner side, the wedge-shaped opening, if of proper size, y, when the normal limit of abduction was d. In this attitude of abduction the limb was by a plaster spica bandage until repair was te. When it was replaced in normal position, clination of the neck was restored and the t was cured.

next step was more direct. It had been strated that the range of normal abduction pendent upon the upward projection of the l neck, and that lowering of the neck checked responding degree this range. In the cases of some duration, particularly those of coxa vara, the restriction is always increased by accommodative muscular adaptation, but eventually by the direct contact of the upper border of the neck and trochanter with the projecting rim of the acetabulum. Thus, in impacted fracture, there is an immediate limitation of abduction which is one of the most significant of the diagnostic signs. If, then, in an early case, the patient being anæsthetized, one were slowly to abduct the thigh, one might, by the means of the fulcrum offered by the rim of the acetabulum and the leverage of the extended limb, actually restore the normal angle. In such a case, the fact that the restriction had been overcome would indicate the removal of the deformity. For although in the normal subject the capsule might be stretched or ruptured, permitting a downward dislocation of the head before the neck would give way, this would be very unlikely if the neck were already broken through. If the deformity were overcome, then fixation for a time in this attitude of normal abduction should assure union with an approximately normal

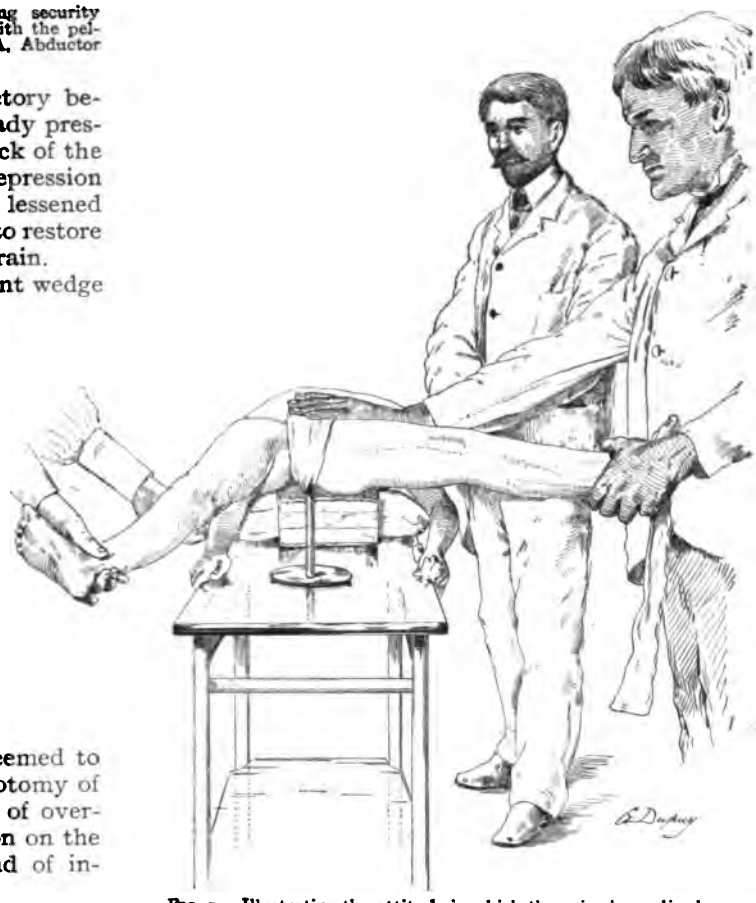

Fig 7. Illustrating the attitude in which the spica is appli ed.

contour. Fortunately, the opportunity to test the treatment was soon offered and it was applied in October, 1901, for incomplete fracture of the neck of the femur in a boy of eight years of age, who had fallen a distance of fifteen feet three weeks before, the characteristic symptoms of shortening, elevation of the trochanter and limitation of motion making the diagnosis evident. The final functional result was perfect, and a Röntgen picture showed restoration of the normal angle.

Not long after, the treatment was applied to a girl of six who had sustained a similar injury after a fall from a second story window, and the result was equally good. These cases were the only ones that I had ever seen or heard of in which there was complete functional recovery after this injury.

The final step was manifestly to apply the same treatment to adult cases, for, as there is no reason to

doubt that traumatic depression of the neck of the femur entails the same penalties at one age as at another, the treatment should be the same. Thus, contrary to the accepted teaching, one should always aim to disengage an impaction in order to restore, as far as possible, the normal contour, for under efficient fixation there should be but little danger of non-union. One might hope, also, that repair would be unaccompanied by the exaggerated formation of osteoid tissue often seen in museum specimens, since it may be inferred that such changes are favored by mal position of the fragments or by inefficient splinting or by want of protection during repair.

If, on the other hand, the fracture were complete, as is common in older subjects, the shortening having been overcome by traction, the limb should then be abducted to utilize the tension on the capsule to direct the outer toward the inner fragment contained within the acetabulum and to bring them into more or less accurate apposition. The attitude of complete abduction makes muscular contraction powerless to induce deformity. This influence, which is described in all textbooks as of great importance, is more directly that of the abductors, the external rotators and the iliopsoas muscles. In abduction the former group is entirely relaxed and impotent while contraction of the iliopsoas would tend to draw the femur directly inward and thus to appose rather than to separate the fragments. Fixation is, however, more directly assured by the contact of the neck with the rim of the acetabulum and of the trochanter with the side of the pelvis. In this attitude the comprehensive support of the plaster bandage should provide the rest most favorable to repair.

This method, at first suggested as particularly applicable to childhood, is now urged as a routine measure for all cases of fracture of the neck of the femur in which local treatment is to be attempted.

It may be noted again that perfunctory treatment or non-treatment is usually excused by the age of the patient; sixty years or even less being accounted old age in this class of cases. It would appear, however, that in most instances it is the probable futility of treatment rather than the condition of the patient that explains neglect, for this, or a greater, age is no bar to operations for other conditions, nor does it prevent the successful treatment of fractures in other situations. For the present discussion, however, let all those cases in which age or other circumstances might seem to contraindicate such treatment be excluded from consideration, for even then, there will yet remain the larger proportion, and by far the most interesting class of cases, since it will include the children and many vigorous adults who now, for failure of diagnosis, are untreated.

The details of application of the method are, in general, as follows: A piece of ordinary seamless shirting, such as is used for plaster jackets, about six feet in length, cut and sewed in a shape to cover the body and the limb, is first applied and is fixed securely in place by bands passing over the shoulders. This is threaded with several long bandages, the "scratchers," designed to keep the skin in good condition. It is also advisable to insert a substantial "dinner pad." The patient is then anæsthetized and is placed in position for the application of the bandage. The head and shoulders may be conveniently supported on a box of proper length and about eight inches in height; the pelvis rests upon a sacral support. This is a thin plate of steel about the size of the hand, of a trowel or heart shape, carried on an upright bar fixed to a wide base or screwed to the end of the table. Such a support is almost indispensable, because it does not interfere with the proper application of the posterior surface of the spica, as do the blocks or other supports in common use. A wide, firm band of cloth is then carried about the perineum, the two ends of which united over the shoulder and held by an assistant furnish counter traction. If the fracture is incomplete, as is usual in young subjects, the limb under gentle traction is slowly abducted, an assistant at the same time adducting the sound limb to prevent the tilting upward of the pelvis, and to demonstrate the normal range. If the fracture is complete, the shortening is first entirely overcome by the traction and counter traction. The limb in the extended attitude, under traction, is slowly abducted by the assistant until the trochanter is fairly apposed to the side of the pelvis; the operator meanwhile pressing the trochanter downward and inward. In some instances there is a distinct snap as the outer part of the neck slips beneath the rim of the acetabulum, and in any event the abduction is increased until the trochanter is firmly apposed to the side of the pelvis. In the first instance the primary object of the abduction is by leverage against the upper border of the ace-

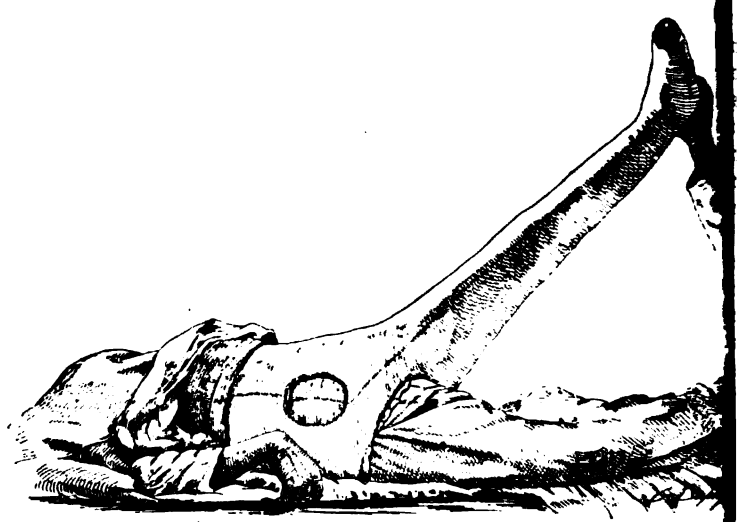

FIG. 8. The long spica as applied for fracture of the neck of the femur in the adult illustrating the advantage of an appliance which permits movement without danger of displacing the fragments; an opening has been made to lessen the constriction of the abdomen.

lum to overcome the deformity; in the second tension on the capsule to remove folds to approximate the fragments and by actual contact of the with bone to oppose re-displacement.

The limb being held in this attitude, the pelvis, ribs, the bony prominences of the knee and foot protected with layers of sheet wadding, and the and body are then covered in carefully with co flannel bandages, which are in themselves a pro tion against pressure. A plaster spica is then plied, extending preferably from the mammary to the toes. This should be drawn snugly about hip, and most important of all, should compl enclose and support the buttock, not only to pro antero-posterior support, but to prevent the exc tions that are inevitable if the tissues are allowed hang over the edge of the plaster. The insertion thin strips of wood or iron about the hip and permits of a lighter bandage than would other be possible. When the bandage is completed carefully cut away to allow complete flexion of sound limb, the shirting is drawn over the edge the bandage, carrying beneath it the cotton, and

ved preferably to an outer cover of shirting drawn er the bandage. Thus a smooth, even surface pposed to the body and the skin may be kept in dition by drawing the friction bandages back forth at intervals. These bandages, popularized Lorenz, are always placed beneath the body part he spica and with the exercise of a little ingenuity ir use can be extended to the limb also.

or greater precaution it may be advisable to cut nings in the plaster at all points where pressure ared, and a part may be cut away from the front he body part if the constriction is too great.

s a rule, the support is comfortable because it ficient, and it permits the necessary movements the patient and even transportation from one ch to another without fear of displacing the frag-nts. In fact, the use of the plaster spica support he treatment of adults is so common in orthopedic ctice that it hardly needs discussion. It is true its proper application requires some care and , but surely not greater than are demanded in r surgical emergencies, nor more than one has ght to expect from those who propose to treat class of injuries.

he long spica is most efficient in that it abso-y prevents rotation of the limb, but the short may be used in impacted or incomplete cases, hich displacement is unlikely, or less burdensome support is red. The steps in the applica-are the same, except that it olded more accurately about the ac crests and the joint, and is especially thick and strong. then cut away so that a band more than four to six inches in h remains across the front of abdomen. The lower extrem-may be carried a little below knee to fix the part more curely or cut away to allow free vement at this joint, if desirable. The short spica permits the patient assume a semi-reclining posture, if the limb were during the plication slightly flexed, it would w the patient to assume practi-y the sitting posture. Such varia-s in technique might be required the condition of the patient.

ne hears much of the physical depression that ws this injury, but this may be due not so much the confinement to bed as to the persistent pain t often follows a fracture which is not reduced and protected, an opinion which is supported by the timony of many of the patients themselves.

If the long spica is used, it may at the end of four eks be shortened to allow action at the knee, and the end of eight weeks, or when it may appear that on is assured, it may be removed.

t this time massage and passive and voluntary tion may be employed, regulated, of course, by the ations of the patient. The limb should not be d to support weight for at least four months. A brace that will permit functional use by support-a part or all of the body weight, combined with sage, is of course the ideal after-treatment. This however, not attainable for ordinary cases, and best routine method is the use of a light, short ster spica holding the limb in moderate abduction. first the patient uses crutches, and resumes weight ring little by little.

In this connection it may be noted that in cases of akness and discomfort either from joint disease injury, simple weight bearing without motion is far less of a strain than weight bearing with motion. In any event, increased and especially persistent discomfort after functional use indicates that the joint is not equal to the work that is required of it. Yet it is an indication that is almost always disregarded, patients being not only encouraged but forced to use the limb even within a few weeks after the injury. If, as in many instances, there is non-union, little harm other than the unnecessary discomfort may result, but if one hopes for approximate restoration of function the natural indications must not be disregarded, and the resumption of activity must be regulated by the symptoms.

The best time for the application of the treatment is, of course, immediately after the injury, for with the comprehensive support of the entire limb, from the toes up, there is little danger of constriction. In fact, it is probable that in many instances the local swelling is aggravated by want of support, and that the persistent œdema of the limb that is occasionally observed is secondary also. If, however, the bruising were extensive, sand-bags and traction might be employed as preliminary to the application of the fixed dressing. The question of after how long an interval treatment may be applied with hope of success, is of far greater importance. It would seem that one could hardly hope to break up an impaction after an interval of more than three months, but it would appear that in certain of the incomplete fractures consolidation is delayed for a long time, as is evidenced by the symptoms of insecurity, and by the pain on motion of which the patient so often complains. The cases of complete separation in which the fragments have never been apposed might merit treatment at a much later time.

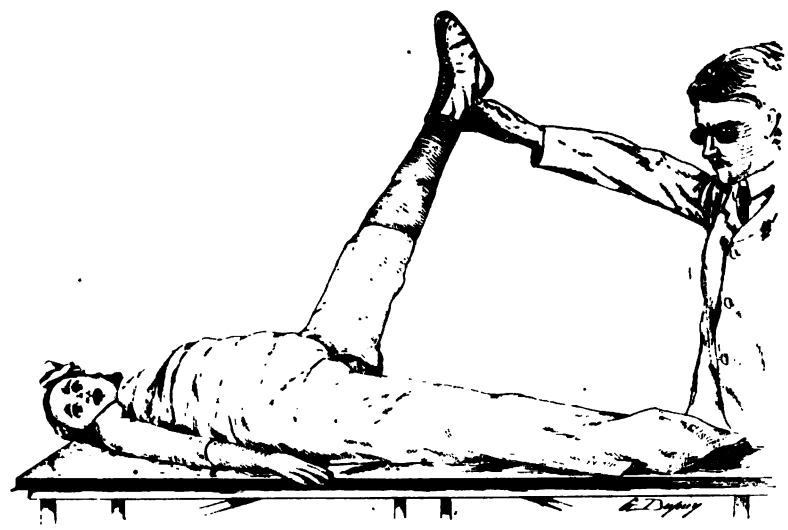

FIG. 9. The plaster spica applied, after reduction of the deformity, in a child: illustrating a greater range of abduction than in the adult. Compare with Fig. 8.

In the review of treatment no mention has been made of the Thomas hip splint. This apparatus, when properly adjusted, is an efficient splint, but except in this regard, it does not fulfil the requirements that are considered essential to success. In this connection it may be noted that it is the attitude in which the limb is fixed and the manipulation that precedes fixation that constitute the novelty of the treatment that has been advocated. The plaster spica is the most practicable means of support, but it might be replaced by appropriate apparatus if this were attainable.

Direct operative intervention is practically a last resort when other treatment has failed, and if the method described has been unsuccessful, the parts, in the absence of swelling and shortening, should then be in the best possible condition for this procedure.

Bissell, in the article referred to, impressed by the futility of ordinary treatment, apparently favors operative exploration as a primary measure, but in any event it would be indicated only in cases of complete separation and it could be applied only under exceptional circumstances. It may be noted that in such operations one is advised to remove the fragments if union seems unlikely and that excision of the head of the femur, in cases of partial epiphyseal separation is classed as a remedy rather than as a necessity of treatment. This indicates an ignorance of the mechanism of the hip-joint and of the ultimate effects of excision upon its function. Excision is justifiable for advanced tuberculosis or other destructive disease and for relief of distortions, as, for example, after unreduced dislocation of the hip, but under almost no other circumstances. The most important function of the lower extremity is weight bearing, and security, even with ankylosis, is much

FIG. 10. Ambulatory treatment with the limb in extreme abduction. In this attitude weight is borne on the trochanter and outer extremity of the neck of the femur. This is the patient shown in Fig. 9.

preferable to free motion with insecurity. Ankylosis does not preclude comfort, security, and symmetry, but motion obtained by excision is often at the expense of all these. For if the head of the femur is removed the shaft is almost always forced upward upon the side of the pelvis and, in consequence, the limb becomes flexed and adducted, approximating the attitude characteristic of dorsal dislocation of the hip. When therefore one, in the treatment of ununited fracture, finds it necessary to remove the head of the femur, he should attempt to secure bony union between the extremity of the neck and the acetabulum, the limb being fixed in extension and slight abduction. If this is impracticable the upper extremity of the femur should be forced forward beneath the tissues attached to the anterior superior spine. This remedy may be applied after the suggestion of Lorenz, without open operation in the cases in which pain and deformity persist after ununited fracture. The position is maintained by hyper-extending the limb and applying a short spica bandage. This support usually enables the patient after a time to walk about with but little discomfort, but from my experience the support must be continued for at least a year to insure the necessary stability.

Epiphyseal separation or fracture is a rather unusual form of injury. It is very uncommon in ear childhood, the injury in such cases being usually the middle or outer extremity of the neck and of incomplete or green stick variety. This is indic by the fact that joint movement is perfectly nor until it is checked in abduction and flexion by distortion of the neck. Whereas, if the articula extremity of the femur were broken or displa motion would be far more restricted, especially ing the process of repair.

In twenty-five cases of fracture of the neck of femur in childhood that have come under my

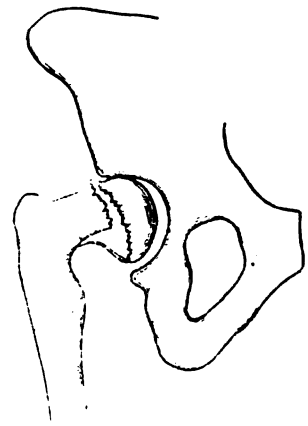

FIG. 11. Complete traumatic epiphyseal separation.

servation, direct, immediate, epiphyseal separa occurred but once. One speaks of immediate physeal separation in the sense of a direct and abling injury, the result of violence in a healthy ject. What is ordinarily described as epiphy separation is very closely allied to coxa vara in onset and in its symptoms. The patients are alm always adolescents, often of the weak and ov weighted type. The symptoms, usually slight li stiffness and discomfort about the joint begin alm imperceptibly sometimes after injury, but of without known cause. After these have persis for a time the patient may become suddenly disab

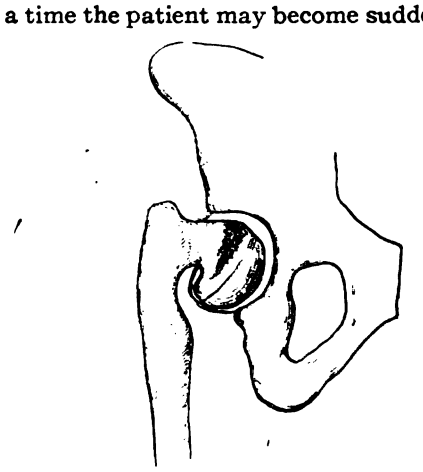

FIG. 12. Epiphyseal coxa vara, in which the deformity is marked on the outer side of the epiphyseal cartilage.

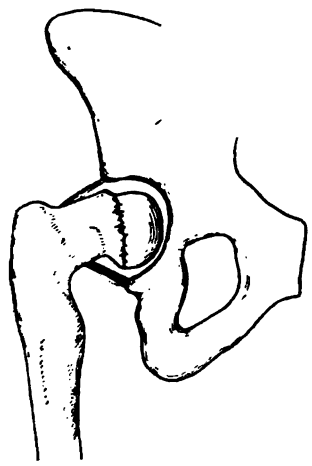
after over-exertion or strain, which, but for the p vious history, would have been credited as the i mediate cause of the disability. In these cases deformity will be found in two varieties. In common form the head of the bone is distorted by giving way of the inner extremity of the neck ne but not at, the epiphyseal junction. A form epiphyseal coxa vara. The other is a true part separation, the head of the bone being displac downward and backward. In cases of this ty motion is greatly restricted. The pain and discom fort are much more noticeable than in ordina fracture or coxa vara. In ordinary fracture t

ıptoms, as in the adult, follow the injury immeely and decrease as repair advances. In episeal separation the first symptoms are not well ked, but they gradually increase until the ient may be disabled. It may be noted that the of the patient is an important element in the gnosis. For it would appear that the epiphyseal tion becomes actually a weak point as the time roaches for its obliteration, when the thick wall artilage that covers it in childhood has been ced to the adult type.

is has been mentioned, the treatment advoed for partial epiphyseal separation, by Sprengel others, is immediate excision, which, from the dpoint of ultimate functional usefulness, is illised. Either one should attempt to replace the d by direct operation, or, if the deformity is not eme, to cut away the irregularities that interfere h motion. It is probable, too, that a simple otomy of the shaft of the femur to remedy the ortion of the limb after repair is complete, would re a more useful limb than that attained by ion.

t may be noted that while the forcible abduction ht be of service for direct or complete epiphyseal ration, it could hardly be efficacious in cases of ordinary type. It has been employed, however,



13. Incomplete traumatic epiphyseal separation, the common form.

h apparent success in cases of rapidly increasing a vara in which it was evident that the resistof the femoral neck was slight.

piphyseal fracture or displacement is numerically light importance, and it is introduced simply to plete the consideration of the three classes of cture that have been mentioned.

In conclusion, attention is again called to the fact t for the purpose of this discussion the application this treatment as that of routine for fracture of neck of the femur is limited to what may be med the favorable class. It is my opinion, howr, that it could be used in practically any case, h the modifications that have been suggested, to ch the methods now in common use might be lied. Doubtless the method would require a ain degree of skill in its application and careful ervision to make it tolerable, but far less than ld be necessary to make the ordinary treatment fil the purpose for which it is used.

At the present time, all patients, whether young d vigorous or old and feeble, are treated, if at all, the same manner. In other words, the limitaas of the aged are extended to the young, whereas young should be treated effectively because they e vigorous, and the aged should be treated effectly, if they are treated at all.

A new treatment must appeal to reason rather ain to experience, and to forestall a probable criticism, it may be stated that it is not claimed that perfect apposition of the fragments is always possible, any more than it is after fracture in other situations where the difficulty of adjustment is far less, or that union can always be obtained, or that distortions can always be overcome, or that the treatment can be applied in all cases, or continued in all cases after it is applied.

It is claimed, however, that improved functional results are far more likely to be obtained than under any other treatment at present in use. The treatment has been proved to be thoroughly practicable,* and whatever may be the outcome, one who applies it will, at least, have the satisfaction of attempting to fulfil under difficult conditions the requirements that are acknowledged to be essential to success in the treatment of the simplest fracture.

*The treatment was first applied to the adult in January, 1902, and last in January, 1904; a report of final results is for the present deferred.

283 Lexington Avenue.

THE SOLUBLE FERMENTS OF COW'S MILK.

By JOSEPH LESPERANCE, M.D. (Paris),
Montreal, Canada.

It is a well-known fact that milk is in itself a complete food, since it contains the three alimentary elements by which all life is sustained, namely, the albuminoids, the fats, and the sugars. But, although human life may be indefinitely maintained by the exclusive use of milk, the seemingly paradoxical fact has been established that an artificial mixture of albumins, fats, and sugars, although in the same proportions as when contained in natural milk, will not sustain life beyond a limited period. The following experiment made by Lunin demonstrates this interesting fact:

Mice, as well as men, can live indefinitely on natural milk as a sole diet. But when they are fed on artificial milk containing all the chemical constituents of an excellent milk, they die in from twenty to thirty days. In this experiment Lunin prepared his milk in the following manner: The milk was diluted with water, and then precipitated by acetic acid. The flaky precipitate was then washed with acidulated water, leaving it a mixture solely of casein and fat. To this quantity of albuminoid and fatty matter, he added cane-sugar in the proper physiological proportion to represent the carbohydrates. Finally he added the salts that are contained in natural milk, in the exact quantities in which they are found in that substance. Theoretically this artificial milk constituted a perfect food, since it contained the three principal groups as well as the salts. Nevertheless, the mice on which the experiments were made did not live, although they relished the diet and ate plentifully of the food.

Lunin was studying the rôle played by the mineral salts in nutrition, and at the time when he announced the results of his experience the scientific world was considerably surprised.

It is now well understood that the factor which was lacking in Lunin's artificial milk, that which was necessary in order to make this product capable of sustaining indefinitely the life of his mice, was that chemically intangible constituent, the active living force, in fact the enzymes or unorganized soluble ferments that were destroyed by his method of preparing and treating the milk. This fact explains why sterilized milk and other sterilized foods have not fulfilled the general expectations of the scientific world. Received at first with enthusiasm by the medical profession, it was gradually shown in the course of time, that they did not

constitute an ideal method of feeding. Many medical men, recognizing the lack of result without knowing the real cause of failure, returned to good natural milk, either simply diluted with water, or not. Careful observation showed that milks that had not been heated beyond a natural temperature were more easily digested, and gave greater vitality to the system. It was observed that sterilized milks produced in children soft muscles, a generally irregular development, and a weakened resistance to infectious diseases. Some men even stated that they were the indirect cause of infantile scurvy. And these unsatisfactory results were observed even when the very best methods of blending were being used, and the milk had been modified so as to make it, from a chemical standpoint, not only merely resemble mother's milk, but actually almost identical with it.

These facts were verified, but without any reasonable explanation of the cause. However, the work and thorough investigation to which milk has been subjected within the last few years, have thrown an entirely new light upon the subject. The constituents which are lacking in sterilized milk, or more properly speaking, are destroyed when the temperature of the milk is raised to 176° Fahrenheit, are the enzymes, those mysterious ferments which govern the equilibrium of the protoplasm. Not only in the animal kingdom, but in the vegetable kingdom as well, every vital phenomenon seems to be dependent on these ferments. The grain of wheat, planted in the soil, owes its development and growth solely to these special ferments. Under the influence of soluble substances secreted by microbes in the bosom of the earth, the grain of wheat emerges from its lethargic condition and becomes a living organism, capable of growth and reproduction. It has been shown that absolutely sterilized earth is useless for the growth of seeds, and that these do not come to maturity in such soil. (Ref. Nobbe, Dresden.)

The same thing applies to the animal kingdom. Animals kept in an aseptic atmosphere and fed on sterilized foods cannot live. The quantity and proportion of albumen, of carbohydrates and of fats may be perfect, but that particular force which separates and disintegrates them into their ultimate terms of absorption no longer exists, and these food substances become inert. According to Kejanitzin, the disastrous effect of the sterilized air breathed, continues even after the animals have again been placed in a normal atmosphere. This author explains, that in breathing ordinary air the microbes inhaled are absorbed by the leucocytes, which separate the ferments which these microbes contain and spread them throughout the organism, where they regulate oxidation and prevent the accumulation of leucomains and other toxic principles.

It is a path abounding in beautiful discoveries that science has opened. It is found that the malignant ferments, producers of illness and death, are in reality only an accident in nature. If there exists those that are responsible for the shortening of some lives, on the other hand their very kin are they that since the creation of the universe have perpetuated species, and finally, the evolution of the higher organisms is corollary to that of the infinitely small. Although there are injurious germs whose secretions disturb the vital harmony and cause a disturbance of the physiological phenomena, yet by way of retaliation or compensation there are a much greater number of those whose secretions are of direct benefit. It is true that, as yet, we know but a small proportion of these, but the list is growing and continues to grow as time passes. Let us salute, *en passant*, the noble germs, creators of fi wines, of good ciders, of fragrant vinegars, and savory beers.

If we have entered somewhat fully into the ab considerations, it is because the ferments that found in milk originate both in the organic cell in the bacterial cell; the former, being necessa in the milk because they are contained in organism and in the gland cells which give ris the milk; the latter, being accidental, but at same time always found in the milk, since they secretions of the bacteria which exists everyw and consequently gain entrance into the m many of them even before it leaves the galactife ducts. These bacterial ferments were thorou studied long before the cellular ferments, and the observations and work of Duclaux are kn intimately. They are for us less interesting t the others, and to them, the cellular ferments, would more particularly devote our attention.

The clear ideas which we at present pos regarding the soluble ferments of milk, have t a long time to come to light. While the first on the digestive ferments of the human alimen canal dates back some fifty years, only five years h elapsed since any serious attention has been g to those of milk. After having discovered pty in the saliva, pepsin in the gastric juice, and tryptic ferments in that of the pancreas, sci rested. Bacteriology acquired a tremendous petus from the ideas of Pasteur; a keen interest aroused that engrossed all thinking minds. B a return to the original ideas, bacteriology discovering the secretions of the microbes, bro these same thinkers back to the study of the se tions of the organic cells, and demonstrated that two are identical, and that there is no biolog difference between the constituent cells of organism, and those minute cellular individu the microbes.

Babcock and Russell of Wisconsin were, so as we can learn, the first to demonstrate the pres of soluble ferments in milk.

In the earlier days the various phenomena t take place in milk were explained as being so chemical—the reaction of one body on anot Then, in the time of Pasteur, the facts becam little better known, and all the transformation milk were ascribed to the action of bacteria. L and Freudenreich made known the consider part played by bacteria in the maturing of Ched and Emmenthaler cheeses.

Babcock and Russell, struck by the fact that the changes taking place in milk could not explained by the activity of bacteria alone, un took a long series of experiments in order to el date the apparent difficulty. They experimen partly with natural milk and partly with milk t had been worked by cheese-makers. To samp of fresh milk they added in some cases chlorofo in others ether, both of them substances wh arrest bacterial growth. They found that coagu tion of the milk set in within a few days witho any corresponding increase of acidity. In th experiments the anæsthetic would have prevent coagulation if that phenomenon were due entire to bacterial life.

Then, as Conn had announced that saprophyt possessed the power of secreting an enzyme anal gous to rennet, and capable of coagulating mil and as Duclaux, in a lenghty communication ha brought to light the important rôle played by th saprophytes in the phenomena of the maturing cheeses, Babcock and Russell determined to inve tigate the question as to whether the coagulatio

the milk in spite of the use of the anæsthetics d been caused by bacteria. They took every ecaution, surrounding themselves with every eguard in order to prevent the contamination of milk by saprophytes. The udder of the cow s carefully sterilized, the first milk was thrown ay, and then the balance was milked direct into ttles containing an excess of an antiseptic prep- tion. By this process the bacteria with spores ich produce the coagulating ferments were ex- ded, and if by chance any of them, coming from lactiferous ducts, reached the milk, they were mediately paralyzed. Under these conditions which ld eliminate all bacterial activity, the same nomena of coagulation and transformation of caseine took place as before, and in the same e. These experiments were repeated with all septics known to arrest microbial reproduction, as fluoride of sodium, salicylic acid, etc., and results were always the same. Moreover, in portion to the age of the various samples of sticized milk, these exhibited a gradual in- se in the percentage of albumoses, formed at expense of the caseine. For example, in milk ve days old, the proportion of the products of digestion was 30 per cent., while in the e milk, two hundred and forty days old, the portion was 63 per cent. Babcock and Russell arrived at the conclusion that besides the nized ferments, there are in milk other fer- ts which are inherent in the milk itself. In uing their investigations further, they found e ferments in the milk of all the mammifers they studied (ass, mare, goat, sheep, sow, falo, and woman). In the cow's milk it is par- ularly abundant and more easy to isolate.

To this ferment they gave the name of Galactase, classified it in the same family as Trypsin, the ncreatic enzyme.

This view of the matter was confirmed in the y same year. Bertrand and Bourquelot, with- knowing anything of the work of Babcock and ssell, demonstrated by other processes the ence in milk of oxidizing ferments. As long as 1881, Arnold had found that fresh cow's k became blue on contact with tincture of guaiac, that this reaction is no longer produced if the k is heated to a temperature of 80°C. In 1890 walesky established undeniably that the same tion takes place in milk when mixed with old pentine. But at that time this reaction was ributed to the presence of ozone. Later it was ognized that free ozone cannot exist in the sys- n, and Bertrand and Bourquelot demonstrated t the reaction of milk toward oxidizing agents due to the presence of a ferment. Of itself it is werless to oxidize oxidizable substances without assistance of an intermediary agent highly ygenated, such as the tincture of guaiacum, old pentine or oxygenated water. But, when these nts yield their oxygen to this ferment, the ter is able to hold it, and in consequence to idize any oxidizable substance with which it nes into contact. For example, if some drops tincture of guaiac are added to fresh milk, this es not change color. But if at the same time me drops of oxygenated water are poured into e milk, a blue color begins to show itself at once. he ferment has absorbed a portion of the oxygen, d coming into contact with the guaiac has idized the latter. Thus this ferment belongs the family of anaeroxydases. At this same time Dupouy, and in the following year (1898) W. Raudnitz, studied this oxydase and found that it is present in the milk of the goat, the cow, and the ewe, and that it is absent, or that its action is very weak in the milk of the ass, the mare, the dog, and in human milk. Marfan and Gillett have also studied this ferment, and confirm its presence in the milk of the cow.

In 1901 Spolverini took up this line of research and recognized in cow's milk the presence of pepsin and trypsin. Working on milk aseptically treated, and in which perfect asepsis was maintained by thymol, he placed in a drying-stove, at 104° F., various quantities of milk, some acidified for the research for pepsin, other alkalized for the research of trypsin. After a certain time he determined the quantity of soluble albumin in it by the biuret reaction. A boiled sample served as a means of verification. By proceeding in this manner, Spolverini found that the pepsin and trypsin were to be met with in all the milks, but were most abundant in cow's milk. The proportion diminishes in the milk of the dog, the goat, human milk, and that of the ass.

Besides these ferments, of which we have already spoken, still another is to be found, which Spolverini identifies with the glycolytic ferment of the blood. If the sugar contained in a given quantity of fresh milk is determined, and the latter is placed in a drying-stove at a temperature of from 38° to 41°C., and the quantity of sugar is again determined after a lapse of twenty-four hours, it will be found that the quantity of sugar has considerably diminished. A portion has been destroyed. This is by the action of a glycolytic ferment. This ferment shows itself fairly active in cow's milk, but slightly less so in other milks. Moreover, in 1901 Luzzati, Biolchini, and Marfan, and in 1902 Gillet, as well as Spolverini, separated still another ferment that belongs to the family of hydrolytic ferments. Under the influence of this ferment monobutyrin resolves itself into butyric acid and glycerin. These authors operated by distilling a mixture of milk and monobutyrin, and in then determining the acidity of the distilled products. They encountered this reaction of splitting up monobutyrin in the milks of the woman, dog, cow, goat, and ass, stronger in the former, and less energetic in the latter. They have agreed upon giving this ferment the name of lipase, a name which Bourquelot had given to a ferment of the same nature, which Hanriot was the first to discover in the blood.

Summing up the various researches and discoveries made in connection with cow's milk, we find then, that this milk contains numerous ferments. We have determined definitely the presence of trypsin and of pepsin, of the lipasic and oxidizing ferments, and of a glycolytic ferment. There is, moreover, reason to expect further discoveries in this direction, and this is not improbable when the extremely complex nature of milk is taken into consideration.

SOME OPERATIVE METHODS FOR THE FIXATION OF MOVABLE KIDNEY AND THEIR RESULT.*

By ALEX. B. JOHNSON, M.D.,
NEW YORK.

Your chairman has honored me by an invitation to present to the society a review of some of the methods used by surgeons for the fixation of movable kidney.

I shall limit myself to a consideration of the principles involved in these operations, to a brief description of some of the commoner variations in technique employed, and to the advantages of some of these variations from a theoretical, and, as far as may be, from a practical point of view. The indications for operations in these cases I shall not discuss. The primary object of operations for the relief of the movable kidney is to permanently fix the organ in such a position that the kidney may continue to perform its functions without the occurrence of mechanical obstruction to its own blood circulation without the occurrence of ureteral obstruction due to bends, kinks, or twists.

And, furthermore, without interfering by pressure or by traction, direct or indirect with the blood circulation of the ascending colon, or with the patency of the duodenum.

If the kidney be fixed in the loin at a convenient point, even though the upper pole be no higher than the last rib, with the inner border of the kidney directed inward toward the median line, or inward and a little downward, so that a sharp bend in the ureter will be less likely to occur, the indications appear in most instances to be accomplished.

It does not appear to be necessary to restore the kidney to its anatomical position in order to relieve the symptoms.

To meet these ends a large number of operative procedures have been devised.

The excursions of a movable kidney may occur within a loosely fitting fatty capsule, or the fatty capsule may remain firmly enough attached to the kidney, while fatty capsule and kidney together may be movable, or a combination of these two kinds of mobility may exist.

All the operations devised consist in exposing the kidney in the loin, with one or two exceptions, by an incision which does not invade the peritoneal cavity.

The incision may be vertical, extending from the neighborhood of the last rib downward to near the crest of the ilium along the border of the erector spinæ muscle, there or thereabouts. The position of the incision is sometimes described as extending along a line four fingers breadth distant from the spines of the lumbar vertebræ.

Other surgeons have preferred an incision extending obliquely downward and forward, beginning above, just below the last rib, and of varying degrees of obliquity, according to the choice of the individual operator, a variable distance, according to the needs of the particular case.

The general direction chosen for this oblique incision has been toward the middle of Poupart's ligament.

*Read before the New York County Medical Association.

Some surgeons have advocated an incision parall to the direction of the fibers of the external obliq muscle, and have exposed the kidney by blu separation of the several muscular layers encou tered; in other words, the kidney is exposed by method similar to McBurney's intermuscular i cision for appendicitis. The kidney may also exposed by a cut below and parallel to the fr border of the ribs.

This incision has been used by surgeons in so cases in order thereafter to resect the twelfth and to suture the kidney to the tissues of eleventh intercostal space, thereby fixing it in position as nearly like the anatomical situati of the kidney as possible. After exposure in wound, the kidney is fastened to the adjacent str tures by one of many procedures. The origi operation of Hahn consisted in dragging the kid enclosed in its fatty capsule well into the wound suturing the divided edges of the fatty capsule the muscular and fascial layers. The wound then closed.

The proportion of failures following this operat led to the development of a large number of spe methods of technique.

They all depend for their success upon the for tion of firm organic adhesions between the kid and the surrounding structures.

While these adhesions are forming it is neces that the kidney should be held firmly in place f number of days.

This may be accomplished by holding the kid in position by gauze packing without sutures, fixation of the kidney depending entirely upon production of granulation tissue, upon the face of the kidney and of the surrounding tissue

The operations of Senn, Jabaulay, and B afford good illustrations of this method.

Senn, after exposure of the kidney throug vertical incision, divided and removed the f capsule. He then scarified the fibrous cap freely with cambric needles. He passed underne the upper extremity of the kidney a strip of ga twelve inches long and two inches wide, placi gauze pad over the exposed portion of the kid and carrying a sling of gauze around the kid fastened it in position over the gauze pad. He troduced two sutures into the upper angle of wound, leaving them untied.

He then packed around and beneath the kid abundant gauze, and placed and bound into pos over the right hypochondrium a pad of suffi dimensions to reinforce the gauze supports.

The secondary sutures were tied upon the t day. The packing beneath the kidney was rem in six days. The gauze sling was removed in el days.

The external wound was then strapped with st of adhesive plaster carried around the body. patient was kept in the recumbent position u the adhesions were firmly organized.

The advantages of this method, as alleged by author, are: (1) An extrarenal support of kidney is obtained. (2) This support is formed union of the fibrous capsule of the kidney with pararenal connective tissue, hence no interfere with the kidney itself. (3) The gauze sling dr the lower pole of the kidney in an outward directio placing the axis of the kidney at an oblique ang with the spine. This position secures support fro the parietal wall at the lower angle of the wou and favors correction of flexion of the ureter.

Another similar operation is that of Beaver. H removes the fatty capsule entirely from the posteri

ace, and as far as the hilum on the anterior ace. He passes gauze beneath the upper pole e kidney, and below the lower, allowing it to in in place for a week or ten days. Gauze is ed around the kidney and the hypogastric ress is employed as in Senn's operation. Heal- f the wound takes place in from four to five s.

is certain that the fixation of kidneys operated by either of these two methods is firm and anent.

another large class of operative procedures the y is sutured to the deeper portion of the d: (*a*) The sutures are made to pass through ibrous capsule of the kidney and the muscular s of the wound (Vulliet). (*b*) The sutures are d through the parenchyma of the kidney ut stripping the capsule (Albarran, Henry is). (*c*) The capsule of the kidney is split, cted off the surface of the parenchyma, and es are passed through the fibrous capsule and uscular borders of the wound, and the wound sed by sutures. (*d*) The fibrous capsule is and stripped and sutures are passed through it, through the parenchyma of the organ, includ- he wound edges, and the wound is closed by es (Tuffier). (*e*) The fibrous capsule is split stripped from the surface of the kidney; its s are sutured to the edges of the wound, and e packing is introduced down to the exposed ce of the renal parenchyma; the upper and r angles of the wound are closed by suture, the central portion of the wound is kept open epeated packing, so that a firm mass of scar e is formed between the kidney on the one hand the abdominal wall on the other. The quan- of packing introduced into the wound is gradu- diminished, and the wound is allowed to in from four to six weeks (Riedel-Kocher).

considerable number of special methods have devised which will receive brief mention. thnot Lane practises a modification of this od. He creates by incisions through the us capsule ten small triangles, the bases of which spond to the surface of the kidney. These gles of fibrous capsule are stripped from the nchyma of the organ, leaving their bases at- ed. The triangles are then twisted and at- ed by means of sutures to the transversalis cles and superjacent structures.

erations which include stripping of the cap- suture of the reflected flaps of fibrous capsule he muscular and aponeurotic structures, and re of the wound by suture, are those of Newman, bson, Law, and Edebohls.

assini, in 1882, fastened the kidney by sutures ed through both the fibrous and fatty capsules. me of the sutures were attached to the peri- um, covering the eleventh rib.

ccherelli, in 1884, introduced four catgut res through the cortex of the kidney.

ne or more of these sutures was tied around the fth rib.

aoli and Buret excised a portion of the twelfth and sutured the proper capsule of the kidney e surrounding parts.

uret added a suture to the twelfth rib.

ulliet of Geneva used a method of fixing the ey which he published in the *Revue Medicale Suisse Romande*, June 20, 1895. After expos- and freeing the kidney in the usual manner, a rate short and vertical incision is made parallel h the spinous process of the first lumbar vertabræ, osing the tendon of the erector spinæ muscle. tape-like slip of the tendon, ten inches long and a quarter of an inch wide, is detached and pulled out through this wound, but is still left attached by its lower end to the muscle.

This tendinous slip is used as a suture and is passed by means of a long straight blunt needle in a handle and with a large eye in its extremity through the muscular tissue intervening between the one wound and the other down to the capsule of the kidney, and having been made to underrun the fibrous capsule of the kidney upon its posterior surface and near the external border, it is then passed back again and fixed to the erector spinæ muscle by means of a suture of fine silk (Carl Beck).

This operation has been used by Henry Morris, and he has also modified it in the following manner: "If too short a length of tendon tears out I have split the width of the tendon and passed each portion separately through the intervening muscle mass down to the kidney. Having underrun the kidney capsule with one length of the tendon, the two lengths of tendon are tightly tied together. The kidney is thus slung into close contact with the lumbar fascia."

Among the numerous methods of special technique is that of Albarran. He attaches great importance to the separation and removal of the fatty tissue which covers the posterior surface of the kidney, with the view that the kidney, denuded of all tissue except its fibrous capsule, should be applied directly upon the anterior surface of the quadratus lumborum muscle. The fatty tissue is removed with the fingers.

When the surface of the kidney has been exposed, three sutures of thick catgut are passed through the kidney by means of a large curved needle. Each suture is passed through the kidney from before backward and includes a liberal portion of kidney tissue.

One suture is passed opposite the middle of the external border of the organ. Of the other two, one is passed above and the other below this point. The sutures are each double, and at the point of entrance and exit of each double thread a double knot is made. When the kidney is drawn up into good position the upper suture is tied around the twelfth rib. The middle suture is made to include both muscular walls on either side of the wound. Likewise the third suture.

It is believed by the originator of this method that the series of double knots prevent the tension exerted upon the ends of the sutures from cutting through the kidney tissue. The tension is supposed to come not upon the kidney tissue but upon the knots. The wound is closed by sutures. The patient is kept in bed for three weeks. The operation of Henry Morris may be described briefly as follows: After exposing the kidney by an oblique lumbar incision a considerable portion of the fatty capsule is removed. Three sutures are then passed deeply into the posterior surface of the kidney—one near the upper—the other near the lower end, and the third midway between the other two but nearer the hilum. Each suture is buried for a length of three-quarters of an inch within the renal substance and penetrates about half an inch into the thickness of the organ. The upper suture passes through the upper edge of the fatty capsule, the transversalis fascia, and the deep layer muscles, and is tied to them. The lower suture is similarly passed through and tied to the lower edges of the same cut structures, and the middle suture is passed through both edges of the wound, including the fascia and the muscles. The remainder of the wound is closed by sutures. The patient is kept in bed from four to five weeks.

Morris reports fifty-seven cases with fifty-seven cures.

The Method of Bazy.—Since 1885 Bazy has practised a method for the fixation of movable kidney which he calls "Nephropexia-en-hamac."

After exposing the kidney by a lumbar incision three catgut sutures are then passed transversely under the fibrous capsule of the kidney at a distance of three-quarters of an inch from one another. The first suture is passed at the middle of the external border of the kidney; the third close to its lower pole, and the second midway between the two. The ends of the first suture are passed at a distance of one inch from one another through the eleventh intercostal space. The ends of the other sutures are drawn through the muscles, close under the twelfth rib, and tied. Thus the kidney is made to lie well up against the ribs. The cellulo-adipose tissue is puckered up by a series of stitches under the kidney and held there by a catgut suture passed through the tissue from outside the muscles below the last rib and tied. Thus the kidney below is supported by a kind of a hammock of fat. On account of the development of scar tissue which follows the introduction of sutures through the substance of the kidney, many surgeons prefer an operation, in which, as in Senn's method, the kidney is fixed in its position temporarily by strands of gauze and gauze packing, and permanently by the formation of cicatrical tissue between the fibrous capsule of the kidney and the surrounding structures. Many of the operations in which the fibrous capsule of the kidney is split and lifted off the surface of the organ, either in the form of two lateral flaps, or in a number of small flaps, or in one large flap, which is drawn through a slit in a neighboring muscle and there fixed by sutures, have been devised with the intention of causing cicatricial union between the bared kidney parenchyma and the surrounding structures without causing any wound of the kidney itself.

As already stated, some of these operations involve immediate suture of the wound. In more than one instance I have had the opportunity to examine kidneys *in situ* which had previously been operated upon in one of these ways involving decortication.

They were very firmly fixed by scar tissue, so firmly that the kidney could not have been torn loose without leaving a considerable portion of the organ behind. I have also had the opportunity to inspect two kidneys operated upon by the method of Riedel, viz., that method, very popular in this country, whereby the fibrous capsule is incised along the convex border of the kidney separated for a moderate distance on either side of the incision from the parenchyma and sutured to the muscular structures on either side of the wound. A somewhat funnel-shaped cavity is thus produced with a surface of naked kidney at the bottom, perhaps two and a half inches long and one and a half inches wide. Upon this surface sterile gauze packing is introduced, the upper and lower angles of the wound are closed by sutures, and the center of the wound, for a distance of at least two inches, is kept open by packing, and thus a considerable mass of cicatrical tissue is formed, fixing the kidney permanently in position.

The patient is kept in bed from four to six weeks. The wound is usually allowed to heal in from three to four, and in the practice of some surgeons not until the end of five weeks. In these two cases also the kidney has been found very firmly fixed in its new position. An observation of about twenty cases operated upon in this way leads me to believe that as far as the fixation of the kidney goes, and freedom from risk in the operation itself, this method leaves little to be desired.

About one-half of these twenty cases have been seen after a considerable interval. In none of them could mobility of the kidney be detected.

Under the safeguards of good surgical technique there should be no mortality as the result of operations for the fixation of movable kidney. That in very large number of operations a solitary fatal result may be expected, as one of the occurrences likely to follow any operative procedure, accompanied by the use of a general anæsthetic, goes without saying.

To select one method of operation as superior to any other is impossible. It is probable that nearly all the methods at present in vogue result in the majority of instances, in a sufficiently firm fixation of the kidney.

Many surgeons believe that sutures passed through the parenchyma of the organ furnish a larger proportion of successes than do other methods of procedure. Among those who entertain this view are Tillmanns, Hahn, Langenbuch, Vaunefville, Tuffier, Frank, Keen, Angerer, Henry Morris, and others. According to the statistics of Keen, of fifty-six cases in which the sutures were passed through the substance of the kidney, thirty-nine were cured.

According to Frank, of thirty-nine cases twenty-one were cured. According to Albaran, who collected statistics in regard to 374 cases, the method in which the sutures were passed through the substance of the kidney were attended by 78 per cent. of cures. Küster, who fixed the lower pole of the kidney to the twelfth rib by means of silver wire, reported permanent and complete cures in 64 per cent. of sixty cases. Kocher's method in nineteen cases reported by Zbuider. Thirteen cases were examined; in all the kidney was fixed. In the fixation of the kidney suture material of the most varied character has been used.

Personally, I believe that sterile catgut offers advantages not possessed by silk or other non-absorbable material. In estimating the value of any particular method of procedure, it is well to bear in mind that the success of an operation, as far as mechanical fixation of the kidney is concerned, is not always identical with a cure of all the symptoms. It is more than probable that many patients whose kidneys have been movable, and who have suffered from symptoms such as are often caused or accompanied by movable kidney, have been operated upon without benefit as far as the symptoms are concerned, and yet their kidneys have been very firmly fixed as the result of the operation. Several such cases have come under my notice.

It is also probable that many patients presenting movable kidneys, and who have suffered from neurasthenic and other symptoms, have been benefited by what I suppose it is fair to designate as the influence of the operation *per se*, irrespective of the question of whether the kidney was firmly fixed or not.

12 East Fifty-eighth Street.

The Alleged Curability of Cancer.—The strong and pessimistic opinion of C. F. Marshall is based on the embryonic theory of cancer. He thinks that parasites take little part in this disease. Mr. Butten and Sir James Paget are quoted in support of the heredity of cancer. Jansen's success in transplanting cancer is not beyond question. On account of the nature of the case, if the embryonic theory is correct, cure of cancer is out of the question, for the embryonic rudiment cannot be gotten rid of. The best treatment is early and thorough operation. The *x*-rays have not been used long enough to determine the amount of recurrence following the treatment. Coley's mixed toxins have apparently caused disappearance of inoperable sarcomata. "I should not expect any better results than might be obtained by dynamite!" This is the author's opinion of radium.—*Treatment.*

STHENOPIA AND HEADACHE FROM EYE-STRAIN.*

By JAMES R. NELSON, M.D.,
KINGSTON, N. Y.

THALMOLOGIST TO THE KINGSTON CITY HOSPITAL; FORMER INSTRUCTOR IN DISEASES OF THE EYE, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

om the time of Paracelsus and Hippocrates to the sent, headaches have been the opprobium of the fession. And suffering humanity still comes efully to the druggist, who goes merrily round his nter to place in their hands the headache-powder aranteed to cure in a few minutes. Or the more ve and dignified doctor prescribes for them some l-tar product, caffeine, *et id genus omne*, with estion of return for another visit in the future, ch does not augur well for a permanent cure. forbears in medicine gave to their patients with dache an emetic or calomel for supposed bilious- , or a venesection or leeches for alleged cerebral estion, thinking that they had got at the causa- factor. We have advanced somewhat to the heroic guarana and other medicinal plants, with bromides and the synthetic analgesics to the end e chapter. But this will not satisfy our patients, demand not simply a few hours relief, but entire nce of the pain which too often makes life not h the living.

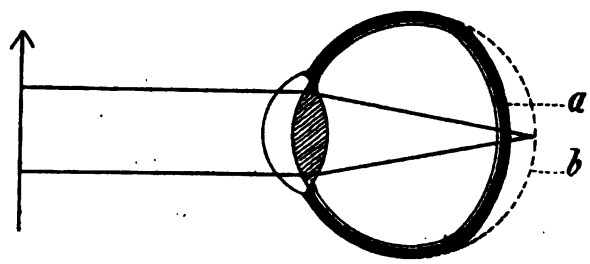
think that the consensus of opinion among ntific medical men of to-day would divide the es of headache, not traumatic or due to cerebral se, broadly into two classes, viz., toxæmic reflex. The toxæmic headaches include, of se, those due to toxic agents introduced from out, such as tea, coffee, tobacco, alcohol, lead, s, etc., as well as those that have their origin in the body—as the headaches of Bright's and gastrointestinal disorders producing toxins. In class of reflex agents, no doubt eye-strain stands mount as a causative factor, not only directly indirectly; through its effect on the nerve cen- , lowering nervous energy, it invites a toxæmic dition, especially that originating in the digestive t, by inhibiting the action of those bacteria ing for us and working constantly in the pro- ion of the antitoxins. For undoubtedly nature ly protects us in this manner from disease. If eyes could be opened like the prophet Elisha to these invisible agents, then would we exclaim him, "they that be with us are more than they be with them."

We get an idea of the progress of medicine if we back only fifteen years and see what was said t eye-strain at that period as a cause of head- e. Take the first edition of Wood's "Reference dbook of the Medical Sciences," and the only rence in the index to eye-strain is in its connec- with the causation of myopia. Let us glance an article on headache in that work, which was to date at that time, by a professor of a Chicago dical school. It is well written, and states many ths as forcibly as they could be stated to-day, and claim any attempt to disparage the brochure. to-day we should explain things differently, our genesis would be on different lines. We should not k so much about idiosyncrasy, and heredity, and peptic headache, and nervous headache in school ildren, etc. There is not one reference to hyper- tropia or the different forms of refractive error oducing asthenopia, or the use of glasses for the e of headache. It is true he mentions "astig- atism," but evidently does not fully understand s import and significance. Let me quote a para-

*Read by request before the Ulster County Medical Society.

graph, showing how near and yet how far he came from realizing eye-strain and its relief by glasses: "A variation from the forms of nervous headache already referred to is that which is observed in school children and students. Many of these are emotionally nervous, dyspeptic, and debilitated, and constantly anxious about their studies. A proportion of them study and live in the stuffy atmosphere of illy-ventilated rooms, which adds to the difficulty. Some have disorders of the eyes that provoke pain on close study. The headache usually occurs each day of study, and is absent or much reduced on the days of recreation. The pain rarely begins with the beginning of the day, but comes on gradually after some hours of work, to disappear after rest and sleep." Those children and students now receive glasses, and are enabled to prosecute their studies with pleasure and not with pain, being relieved of their "emotionally nervous state."

What do we understand by "eye-strain?" It is a complex affair, but briefly I might say that it is a reflex disturbance of the nerve centers due to malformation, either congenital or acquired, of the visual apparatus, associated frequently with an imbalance of ocular muscles, and also hyperæsthetic or paretic conditions of the ocular end bulbs and their accessories. This may manifest itself in multitudinous ways. Locally, symptoms of eye-strain are shown by the red eyes with scales on the lids of children and youth, blepharo-conjunctivitis we term it, by styes, chalazia and pterygium, twitching of the lids, swelling and drooping of the lids, etc. And in the aged, cataracts no doubt often owe their origin to ill-fitting glasses and the resulting strain. The



a. Posterior wall of far-sighted eye, too short in antero-posterior diameter. *b*, Dotted line shows wall when acted upon by muscles of accommodation, giving perfect vision, the rays of light from the arrow coming to a focus on the retina.

watering eyes and weak eyes, the eyes intolerant of light indicate often that glasses are needed. Particularly is eye-strain manifest in any lowered condition of the system—after an illness or an injury, or in anæmic, rheumatic, or other blood dyscrasia. Physicians, I think, often make a grave mistake in allowing convalescents to read too much, especially while in bed, which should be avoided always.

We say pain is the crying out in emphatic protest of a functionally disturbed nerve, and asthenopia may cause neuralgia in nearly every part of the body, over the heart, in the neck, the back, the face, etc. The headache from eye-strain may be in any part of the head, most frequently, I think, frontal or supraorbital, and it may be of any degree of severity. We may have dizziness, impaired mental power, an erratic and irritable disposition, skin eruptions, gastric disturbances producing toxins and thus establishing a vicious circle which tends to perpetuate itself. The neuroses of eye-strain are legion, more marked perhaps in children as we see in choreiform movements and other manifestations. The irritable hypochondriacs, the queer people, the neurasthenics, the Carlyles, and other miserable people are the victims of eye-strain. A smile of incredulity may be caused by claiming eye-strain as the parent of so many of the reflex neuroses, even epilepsy as claimed by some. But the person who, after taking the whole

list of drugs, has been restored from an agony of pain or an irritably nervous state to a condition of general well-being by proper glasses or restoration of muscle balance, is sufficient answer to the carping critic.

Does perfect vision, that is $\frac{20}{20}$, indicate there is no eye-strain, and no need of glasses? Not at all. I will explain by a diagram how the patient *makes himself see* $\frac{20}{20}$ by using the muscles of accommodation sufficiently to overcome the real defect. Take the far-sighted eye as an example, which is too short in its antero-posterior diameter. If you take a rubber ball in your hand and make pressure upon its equator, it elongates at the point of the least resistance; just so the patient with the far-sighted eye, exercising his muscles of accommodation, elongates the eye and enables the focus to come upon the retina. Some may carry this handicap and for a long time feel no ill effects, but let such a person call on the eyes for extra work, as in bookkeeping, stenography, studying at late hours or in a poor light—especially German, Greek, or music. Then the handicap begins to tell. The amount of refractive error or muscular insufficiency does not always indicate the degree of eye-strain. Occupation, age, general condition of the system, and the personal equation are large factors in the case. Some cases are apparently paradoxical. For instance, Mr. S., age twenty-five, a Harvard graduate, came to me for an annoying nictitation of the lids. He had gone through his college course with no eye-strain, and had supported himself by his own efforts—teaching, tutoring, etc., this involving of course extra work for the visual organs. But a year or two after graduation, when he applied for a position as principal of an academy, the committee told him frankly they could not accept him, despite his attainments, on account of the constant winking of his eyes. This meant a loss of $1,500 a year, and you can imagine that he felt badly about it. I was able to remove the disability by cylindrical lenses. Now, why did not his eyes give out when in college? Another case similar to the one just cited, a young lady, age twenty-four, who had taken a college course, complained of dizziness. I found that she accepted a plus 1.50 spherical, which entirely relieved the vertigo. Now, why did she not require glasses during the years she was constantly studying? One patient with a large amount of error will have no eye-strain, while another equally robust and strong with a very slight error will be relieved of headaches by the proper correction.

These seeming paradoxes and contradictions can be explained by the oculist. And just here let me say it is the province of the oculist not only to make out the refractive error and give the proper glasses, but at the same time, as a physician, to remedy by proper treatment those morbid conditions disclosed by his examination. It may be a toxæmic or lithæmic state, or an interference with tissue metabolism, or a change in the blood-pressure, or any morbific tendency. If the case is sent by the family physician, refer the patient back for treatment with such suggestions as the case indicates.

To whom should the physician send his patients with eye-strain, to the oculist or the optician? In other words, who should fit glasses? The oculist has spent many years of his life to fit himself to graduate as a physician and surgeon, and after a few years of general practice has devoted more years in study and service in eye and ear hospitals to fit himself as a specialist on the eye. The optician takes a three weeks' course in a wholesale optical house on Maiden Lane and calls himself an "eyesight specialist." Does the physician send his ca of fracture to the manufacturer of splints? Does send cases of curvature of the spine to the instrum maker to have a plaster-of-Paris jacket applied to the orthopedic surgeon? Does he send patient with lung trouble whom he desires help with the best skill attainable to an "expecto tion specialist," or one with heart disease to the "palpitation specialist"? Is this absurd? No m so than sending patients requiring glasses to optician, be he "R.O." or "eyesight specialis Valuable time is often lost in the detection treatment of disease, as every oculist well kn who has found his patients sent to him for eye amination suffering from what was not even pected, viz., Bright's disease, glaucoma, diabe cerebral disease, or one of the long list of le ailments.

In the textbooks used by the so-called "opt schools," I see much space is given to the diagn of glaucoma. They are laymen; is it expecte these "eyesight specialists" that they pra medicine? Many of them gravely give opinion as to the crystalline lens, the optic nerve, and I presume prescribe for their "patients," in grateful recognition call them "doctor." I this from the fact that while in the store of a w sale optician, he, not knowing me personally oculist, tried to sell me medicine put up for eye, supposing that I was an optician. The fi of glasses is a branch of the practice of medi and to perform it properly not only involv knowledge of lenses and optics, but of the disea the eye, and in fact of all the ills that flesh is he in this complex and intercorrelated human b where each organ sympathizes with and is depen on the other—a knowledge gained only by long y of study and experience in the science and pra of medicine.

DILATATION OF THE BLADDER IN SUP PUBIC CYSTOTOMY.

By E. BLASUCCI, M.D.,
NEW YORK.
VISITING SURGEON TO THE RED CROSS HOSPITAL.

THE modern tendency in surgery to perfect t nique under the guidance of asepsis has bro about remarkable changes in the surgery of bladder. It is only a few years since the method of Franco was revived, because of the which the opening of the peritoneum in suprap cystotomy had always inspired, and we see to surgeons of prominence in this country and ab giving up the only method which safeguards integrity of the peritoneum—the dilatation of bladder. Is this a simplification or the omi of an essential of the operation?

Let us consider, first, the reasons for this cha It has been claimed: (*a*) That the method of liga the penis on the catheter might endanger the pora cavernosa; (*b*) that an injection may cau congestive state of the bladder; (*c*) that the pres of the liquid in the bladder might cause the orga burst; (*d*) that the ascension of the peritoneal de-sac does not always occur in proportion to bladder inflation; (*e*) finally, that there are case which the distention cannot be practised, viz., operation on the female; fistulous bladder; fract of the urethra and bladder by trauma; stone i pacted in the prostatic urethra.

Laying aside the objection of the danger to penis, concerning which no cases are registered my knowledge, and the objection of possible co

estion of the bladder, for which I could find no irect cause with a proper injection, I will direct y attention to the bursting of the bladder, this nergency having occurred to such a skilful surgeon Guyon.

The capacity of the bladder has been the object the researches of a good many anatomists, who ve obtained the most discordant results, the ures ranging from 200 (Krause) to 3000 cc. aulet). Bouley states that the bladder bursts der an injection of from 850 to 1700 c.c. In actice, however, these anatomical researches have tle or no value, since the reflex contraction of the dder, and not the distention is the cause of the rsting. Therefore, Delbet, in his experiments, asured what Guyon calls the "physiological capay of the bladder," that is, the quantity of liquid be injected in order to produce an impelling desire pass urine. His results give an average of 350 c.c. es in which the bladder did burst under a smaller ount of liquid are very few, and in all of them, the one related by Guyon, an undue pressure applied. Concluding, we may say that an ction of from 200 to 250 c.c. of liquid, *under com- anæsthesia*, is harmless. If, however, we pre- sly measure the bladder capacity of a subject, may feel sure that the amount measured cannot e the bladder to burst under anæsthesia, pro- d muscular relaxation be complete.

ut what is, in practice, the quantity of liquid ired in order to have the peritoneal cul-de-sac iciently raised above the pubis to permit an easy neuver? The researches of the anatomists on point give also the most discordant results. ording to the opinion least favorable for the sur- n, the cul-de-sac rises 1 cm. above the pubis der an injection of 200 c.c., while with an empty dder it remains as far down as 2 cm. below the bis. These anatomical experiments evidence the vantages of the injection; the figures show that se advantages may still be obtained through an ection below the limit stated. It is obvious that, th an empty bladder, to get at the peritoneal fat dden behind the pubis and to detach at that depth e cul-de-sac and push it upward in order to lay e the anterior surface of the bladder, must be a y difficult task. Tissues in a state of distention be much more easily attacked than tissues in axation. Work under these conditions would n voluntarily increasing the difficulty of the ration, while in a spasmodically contracted bladd- an injection of only 50 c.c. would be of great help ing the operation. Finally, all anatomical ex- iments lack the one condition of greatest impor- nce, viz., the normal vital elasticity of the bladder. As is well known, this organ when empty, is flat d triangular in shape. This condition varies but tle, if at all, with a moderate injection on the daver, while the same amount of liquid injected a living subject causes the bladder to assume an oidal shape more or less, according to the sensi- eness of the bladder. After an injection of 150 c.c. liquid in a young subject with thin abdominal alls, we can feel the bladder plainly above the bis, while we cannot feel it as well on the cadaver. here is, then, a fact in the living subject not de- rminable on the dead body which favors the cension of the bladder, and it is this physiological ct, not the injection itself, that causes the peri- neal cul-de-sac to rise above the pubis. This fact annot be determined on the dead body. There- re, even in cases in which the injection meets with reat resistance through exaggerated reflex contrac- ion, I should still think it advisable to inject a small amount of liquid, since a higher elevation of the cul-de-sac would follow than in an ordinary bladder after the same injection.

We have now to consider those few cases in which the injection cannot be carried out, at least to the full extent; and finally those cases in which the catheter cannot be inserted for pathological causes inherent to the urethra itself, or because of stone—impacted in the prostatic urethra. In this last case median perineal lithotomy is the easiest and most appropriate operation. In cases of difficult catheterization, the bladder is generally in a state of distention, which favors the operation. In the other cases (operation on female, fistulous bladder, and bladder torn by trauma), I would emphatically recommend the ingenious instrument of Dr. Vetere of Naples, which was presented at the Eleventh International Medical Congress of Rome, 1900, and which seems to have given the most satisfactory results. It is a catheter carrying at its vesical extremity a collapsible balloon which can be hidden in the shaft and inflated after the catheter has been inserted. The maneuver is very simple, and it has also the advantage of preventing the effusion of liquid in the suprapubic wound when the bladder is opened.

In conclusion, I feel safe in asserting that (1) A careful injection is of no danger to the bladder. (2) A limited dilatation of the bladder is preferable to none. (3) Anatomical researches in regard to the ascent of the peritoneal fold are of little or no value for the surgeon, and in practice we find more working space than by these researches we should suppose. (4) There are practically no cases in which suprapubic cystotomy is indicated, in which dilatation of the bladder cannot be carried out.

GASTROENTEROSTOMY FOR CARCINOMA OF THE STOMACH.

By W. P. McINTOSH, M.D.,
PORTLAND, ME.
SURGEON PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

James B., admitted August 1, 1902, aged forty-three years, nativity England. Family history: Father living, in good health; mother died at age of eighty; no hereditary tendency to disease.

Personal history: Has never had any venereal disease. Has had several attacks of malarial fever, was in this hospital for two and one-half months the first part of this year suffering from a grave form of anæmia, as indicated by the blood count and estimation of hæmoglobin. At present his skin has a sallow, dirty, yellowish color, and seems too large for his frame. He is much emaciated, and being a very tall man, one is at once impressed with this fact. The most urgent symptom of which the man complains is great weakness, he does not feel as if he could stand or walk. The mucous membranes are pale and flabby, and the hair and nails long. The bowels are constipated; he vomits his food occasionally, but has never vomited any blood. He says that he has no pain at all, only an intense weakness. The spleen and liver are slightly enlarged, the other organs appear to be normal. There is no tenderness over the stomach. He suffers greatly from ulceration of rectum and piles. There is no rise of temperature (37.2), the pulse is 80. The patient was given a calomel purge and put on a tonic of strychnine, arsenic, and iron.

August 5. The man vomits occasionally, but on the whole seems to be gaining ground and is able to be out. The stomach is somewhat dilated.

August 29. There is a sensation of fulness and pressure in the epigastrium, with at times a dull pain. The patient has been getting easily digested

and nutritious food, but, in spite of this, vomits about an hour after each meal. Bodily weight and strength are somewhat diminished. Test-breakfast shows very little hydrochloric acid. For several days the stomach has been washed out and this has seemed to give some relief. The symptoms point strongly to carcinoma of pylorus. There is no blood nor coffee-ground matter in the vomited matter. There is a lump or tumor just above and to the left of the umbilicus, pressure on this causes some pain, it is movable, irregular, and hard.

Operation: A straight incision was made directly over the tumor. Direct inspection and palpation of the tumor revealed a hard nodular mass occupying the whole of pyloric end of stomach. The intention was to do a pylorectomy, but the extent of the disease and the condition of the patient contra-indicated this procedure. Gastroenterostomy was decided upon as most feasible. A small opening was made in the posterior wall of the stomach; through this opening the index-finger was introduced, and an attempt was made to dilate the pyloric opening, but this was found to be impossible without the use of undue force. By starting at the pylorus and following along the intestine, there was no trouble in selecting the point in the jejunum at which it was desired to make the anastomosis. This saved time, and every minute of time saved in operating on the stomach gives the patient a better chance of recovery. A portion of the intestine (jejunum), about twenty inches below the pylorus, was selected, an incision about half an inch in length was made in it and one-half of a Murphy button was slipped in and held with forceps while a purse-string suture surrounded it; the other half of the button was then fixed in the gastric incision in a similar manner and the two halves of the button were snapped together. Lembert sutures were used to approximate the serous surfaces entirely around the button, and the operation was complete. Silk sutures used throughout. The idea of using as short a piece of gut as possible below the pylorus (having a due regard to getting far enough from the diseased area) was to prevent the formation of the "vicious circle." The patient reacted well.

The stitches in the abdominal wound were removed September 11. On the following day the patient sat up and walked across the room twice. On September 20 he ate solid food. Patient did not vomit at any time after the operation; his appetite was good, and he slept well. No appearance of Murphy button.

October 1. No button yet. *X*-ray shows dark spot in stomach—probably button. Eats steak, etc.

October 11. Patient has attack of acute intestinal indigestion, abdomen swollen and tympanitic, some pain. The scrotum was swollen and discolored and slightly painful. A high injection of asafœtida was given, and the bowels moved twice.

October 12. Somewhat improved this morning, tympanites is disappearing. No reason is apparent why the scrotum should have become very much swollen, tender and discolored, unless the patient injured himself, but he says not.

October 13. Tympanites is still present, but a rectal injection of quinine and aromatic sulphuric acid restored tone to the bowel and relieved the tympanites.

The patient lived for three months in comparative comfort from time of operation, and never vomited once after operation, although he had vomited after each meal before. The vicious circle was not established, much to our gratification.

The man died November 30. The Murphy button was found in the stomach. The pyloric opening was almost completely closed. The mesenteric glands were enlarged. There were no metastases.

PRIMARY PYELITIS IN INFANTS.

By MARCELL HARTWIG, M.D.,
BUFFALO, N. Y.

THOUGH there may be possibly some mention of this disease in the literature, I am not cognizant of such fact. Post-mortem, two cases were found to my knowledge (Wendt and Northrup). Primary nephritis has been described by Holt and Jacobi but of this I do not speak. I cannot devote the time for extensive searching of the literature, but having been a pretty steady reader for thirty years it strikes me very peculiarly that I have never come across a statement regarding the occurrence of this affection, although my impression is that it is not so very rare. It is possible, however, that I have overlooked cases in bygone years. Since I recognized the first case two years ago I have seen two more.

Evidently the failure to recognize the disease (which was not known to Ewald when he honored us in Buffalo with a lecture some six months ago) depends on the fact that nothing but a careful urinary examination reveals it, while its general impression is that of typhoid fever. Nothing seems indicative of urinary trouble, and so the urine, difficult to obtain in babies anyway, is not demanded for examination. A superficial examination may even fail, as the amount of albumin is very small (in girls it might be considered of vaginal origin) and the turbidity is insignificant. Only the failure to come to a diagnosis after a negative Widal test prompted me to examine the urine more carefully in the first case. This patient was a boy, the next two were girls. The first and the third children were practically breast-fed, the second patient, who was somewhat older, was only partially breast-fed. The urine in each case had microscopically all the characteristics of pyelitis, swarming with bacteria when entirely fresh. I regret that I cannot state what kind are the real offenders; but Dr. T. J. Carpenter, who started the task of identification in the last case, had to give it up, and new material has not been available since. The colon bacillus and the fluorescens liquefaciens seemed to be present.

Not until Rovsing had shown that a kidney could be infected by an injection into an ear vein, could we understand the appearance of such a pyelitis. Now it remains to determine the point of invasion, and this is certainly a desideratum which will not be readily fulfilled, as all my cases but certainly cases one and three, were in especially healthy children of excellent stock, without anything extraordinary occurring at the onset in each. In each case I thought for the first few days that I was dealing with typhoid fever. The duration was about one month in each, until the recovery could be called perfect microscopically; while two weeks in two cases, and ten days in one, comprised the feverish periods. The fever was quite high in each case (up to 105° F.), and required antipyretic remedies. The recoveries I attribute to the use of antiseptics, turpentine, and urotropin, though nature might have possibly succeeded alone. Case two had, about six weeks after recovery, an abscess under the ear, whether as a sequel or not I cannot say. The others remained well without sequelæ. The temperature was generally highest in the evening.

In conclusion I would urge the profession in all doubtful cases of typhoid fever in infants to examine the urine for primary pyelitis, and they will probably frequently solve the conundrum of a "continued fever" in infants.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

LOOD CULTURES IN THE DIAGNOSIS OF TYPHOID FEVER.

HE isolation of typhoid bacilli from the blood of ose suffering from typhoid fever marked a new era the history of this disease. Attempts in this ection have yielded such a high percentage of itive results as to leave no doubt that this bacil- is present in the general blood circulation of all hoid-fever patients. Typhoid fever must there- be regarded as a septicæmia. This conception clusively negatives the value of attempts at intes- l antisepsis as a primary factor in the treatment he disease. We now know that if we are ever possess a specific typhoid treatment an agent t be forthcoming whose action shall be exerted nd through the general blood circulation. Shortly owing the first successful endeavors to isolate the illus from the blood great interest was manifest cerning the value of such a procedure from the ndpoint of diagnosis. Observations have now n sufficiently multiplied to warrant a definite ion with respect to this important matter. The s show that the bacillus can be isolated from the od much more frequently in the first and second ks of the disease than at a later period. In the t week the number of positive results has been h (from 70 to 90 per cent.). From this it is seen t the diagnostic value of this method applies fly to the first two weeks of the disease and is ely concentrated within the first week. In order btain a correct opinion of the practical value of od cultures in the early diagnosis of typhoid fever mber of circumstances must be given careful con- ration. Experienced clinicians will agree that ability to diagnose typhoid fever within the first k of the disease, leaving blood cultures out of sideration, stands at the present day approxi- tely as follows: At least 50 per cent. of all cases be diagnosed on or prior to the seventh day by aid of clinical history and symptoms alone. Of remaining 50 per cent. at least 45 per cent. can diagnosed within this period if in addition to the ical history and symptoms the Widal test, the l and differential leucocyte count, the isolation the typhoid bacillus from the fæces, and the diazo- ction are brought into play. This means that thout the aid of blood cultures and by utilizing all her known means at least 95 per cent. of all cases n be correctly diagnosed within the first week. om a consideration of the records of those cases ich have been carefully followed from the begin- ing it is certain that these figures are conservative ther than otherwise. An investigation of those not so diagnosed will show that in the vast majority one or another of the means mentioned were not employed. Granted that there are 5 per cent. of cases which could not be diagnosed within the first week without the aid of blood cultures, it is certain that practically all of this 5 per cent. could be positively diagnosed without such cultures before the end of the second week. For it must be remembered that in the second week the value of the Widal test, the leucocyte counts, and the isolation of typhoid bacilli from the fæces is tremendously increased. The case of typhoid fever should be very rare which cannot be diagnosed by other means than blood cultures prior to the end of the second week. This statement does not apply to the isolated use of any one test, but it applies in the careful use of all laboratory tests, excepting blood cultures, when the results of such tests are considered in connection with the clinical picture and history. So far then as the value of blood cultures in the early diagnosis of typhoid fever is concerned, it is limited to 5 per cent. of cases which could not be otherwise diagnosed in the first week, but in practically all of which the diagnosis could be reached without blood cultures before the end of the second week. Now the circumstances which surround the proper carrying out of blood cultures is such that in private practice at least they ought not to be resorted to except under dire distress and when all other means have failed. At least 5, and preferably 15 c.c. of blood must be taken from the patient. From his standpoint this is a procedure of considerable moment and ought not to be performed unless absolutely necessary. There is in reality only one class of cases in which such a necessity exists—those cases which are first seen in the first or second week and in which the diagnosis rests between typhoid fever and a condition which requires immediate operation and in which all other means have failed to give a positive diagnosis. Such cases are extremely rare, but in them blood cultures are not only justifiable but demanded and ought always to be resorted to. For the late diagnosis of typhoid fever blood cultures possess but little value both because the bacilli at that time can not nearly so frequently be obtained from the blood as at an earlier period and because in practically all cases the diagnosis can be made by other means.

It is thus seen that blood cultures as a means in the diagnosis of typhoid fever ought not to come into general use, especially in private practice, and that their actual utility is limited to a very small number of cases.

CONTAMINATED VACCINE VIRUS.

THE purity of vaccine virus is a matter of vital concern to every practitioner of medicine. The laity are inclined to hold the physician responsible for any untoward consequences which may follow a given vaccination. While this is not strictly just, it is, nevertheless, a condition which must be faced and intelligently met. Recognizing the necessity for care, most physicians are painstaking in the selection of the brand of virus which they use, and perform vaccination with as great aseptic precaution as pos sible. They are justified in demanding that the virus which they purchase be free from contamination. In this connection the observations of W. T. Howard, Jr. (*Journal of Medical Research*, January, 1904),

deserve careful thought at the hands of every practitioner. Howard examined, bacteriologically, from October, 1902, to May, 1903, the vaccine from five establishments in the United States. Some of this virus was bought upon the open market in sealed packages. Other specimens were submitted by the Health Department of Cleveland, Ohio. They were likewise samples of commercial vaccine. The samples consisted of both ivory points glycerinated tubes. The virus of all these establishments was contaminated with actinomyces, although every sample did not show such contamination. In all there were examined ninety-five specimens, twenty-four of which were thus infected. Those specimens which showed the greatest bacterial contamination also showed the largest number of actinomyces. The latter organisms which were isolated are to be separated into nine different species, six of which have apparently not been hitherto described. Their pathogenesis for man has not as yet been definitely determined. The source of this contamination is probably multiple. As actinomycosis of calves is uncommon, it is improbable that actinomyces reach the virus from actinomycotic processes in the calf. Calves from actinomycosis infected herds may, however, possess upon their hides these microorganisms, which, in this way, are brought to the vaccine establishments. Thus actinomyces may be transmitted in such an establishment from the vaccinal lesions of one calf to those of another. In this way all of the virus would become contaminated. The water, utensils, and instruments used in the preparation and storage of the virus are also possible sources of contamination. The most probable sources, however, are to be found in the air, water, soil, hay, and straw with which the calves come into contact.

The importance from the viewpoint of the practitioner which attaches to Dr. Howard's results lies not so much in the pathogenic or non-pathogenic properties for man possessed by the actinomyces isolated, as in the conditions which make such a contamination possible. It is obvious that conditions in a vaccine establishment which allow contamination with actinomyces and permit such an infected virus to be sold, also permit of contamination and sale of virus containing microorganisms highly pathogenic for the human being. It is to be regretted that the names of the establishments offering the contaminated virus are not made known in Dr. Howard's article, for the medical profession have a right to protect themselves against the use of such products. In this day and age no excuses can be forthcoming which can justify in any way the production and sale of contaminated vaccine virus.

SANITARY CONDITIONS AND THE DISEASES COMMON TO THE ISTHMUS OF PANAMA.

INCLUDED in the report of the Surgeon-General United States Navy for 1903 is a paper by Dr. Herbert O. Shiffert, Assistant-Surgeon U. S. N., dealing with the Isthmus of Panama from a hygienic standpoint. That the Isthmus of Panama and the country abutting thereon is unhealthy, is a fact too notorious to need further emphasis, but seeing that ere long Americans will most probably be working in this same country, all information procurable concerning its sanitary conditions and diseases must be regarded as most valuable. To be forewarned is, with the wise, to be forearmed, and when it is definitely known what diseases will have to be fought, and the nature of the sanitary conditions which must be met in and around the Isthmus of Panama, proper and effective steps can be taken to preserve the health of those engaged in the construction of the proposed canal. Dr. Shiffert states that the isthmus, or rather the country along the railroad, is in a fearful condition. For the first twelve miles along the railroad and proposed canal route the country is low and marshy, and affords an admirable breeding place for mosquitos, which are present in swarms, and among their number are a great many of the genus anopheles. The result is that malaria is endemic, particularly the pernicious type. The diseases common to Colon and the Isthmus are as follows, and occur with frequency in the order named: malaria; remittent, intermittent, and pernicious fevers; smallpox, yellow fever, catarrhal dysentery, leprosy, and elephantiasis.

Edwin Emerson, Jr., writing in the *Criterion*, December, 1903, draws this picture of the Isthmus and vicinity: "On the whole face of the globe there are few more wretched places than the narrow slip of marsh land and jungle known as the Isthmus of Panama. Unhealthy enough in itself from topographical causes, the Isthmus has long been a breeding ground for all the worst diseases that afflict mankind. Yellow fever, smallpox, malignant malaria, tuberculosis, with other loathsome diseases, are common, while every now and then there are sporadic outbursts of Asiatic cholera, leprosy, and the bubonic plague. This is due, in part, to the constant transit of passengers from the infected regions of South America and Asia, partly to the unhealthy conditions wrought by the excavations and draining along the line of the projected canal, and again to the physical degeneration of the mongrel population that has in years past been drawn to the Isthmus."

From interviews with Colon physicians Dr. Shiffert obtained the following facts with regard to the occurrence of yellow fever: It occurs in epidemic about once every three years, the epidemics varying in intensity. It never originates in Colon, but has been repeatedly traced to Panama, thence to Guayaquil, the principal port of Ecuador. It is regarded as particularly fatal, and the Colon physicians state they never saw a patient recover. Information however, with regard to yellow fever in and around Panama was very unsatisfactory, and the writer thinks that it is less frequent than is generally supposed, and further believes that the disease is often confounded with pernicious malaria.

Intestinal disorders seemed to be limited to what is known as epidemic diarrhœa, probably simple catarrhal dysentery. Leprosy seems to have gained quite a foothold in the country, and the American minister at Bogota told the writer that about 30,000 people are lepers and that no effort is made to isolate them.

The preventive measures suggested by Dr. Shiffert are, among others, these: The purchase of five miles of territory on either side of the proposed route, in order to have a sufficient area under the laws of the United States. The numerous small towns that now line the railroad would then have to abide by adequate sanitary laws, and the many ways by which the disease is now propagated would then cease to

exist. The author is of the opinion that such a scheme would not only protect the laborer who will dig the canal, but after its completion would afford protection to those in transit and so to the whole world.

The next great object would be to rid the country of mosquitos, either by draining the swamps and other infested places, or, if this could not be done, by killing their larvæ by the best means which experience in our own country and Cuba has taught us. The writer does not believe that the swamps can be satisfactorily drained until the canal is complete, for the reason that there is an enormous rainfall during the entire year, the only difference between the wet and dry seasons being, that in the latter it rains most of the time, while in the former it rains all the time. If it is found impossible to destroy the mosquitos, then measures of protection against their bites must be taken.

It would seem then that all who are acquainted with Panama are agreed that it is one of the worst pestspots on the face of the earth, and that unless energetic steps are taken by the United States Government to put into force measures to render the locality less deadly to human life, the holocaust during the making of the future canal will approach in magnitude that which marked and disgraced the partial carrying out of de Lesseps' project. As soon as the Panama route is decided upon—if ever—advice should be taken of sanitarians, engineers, and physicians as to the most efficient means of protecting the canal laborers from disease. Such advice should be acted upon before work is begun.

Smallpox Hospitals and Aërial Convection.

In a lawsuit recently brought in England against the city of Nottingham, for allowing a smallpox hospital to be situated within fifty feet of a public road, thereby constituting a menace to passers-by, numerous medical authorities gave evidence. The testimony was somewhat conflicting, although the weight of the evidence was in support of the contention that the existence of a smallpox hospital in proximity to a road is a source of danger.

Dr. J. C. Thresh, in the course of his examination as witness, said that in his opinion the zone of danger, with forty persons in a hospital, would on occasions extend beyond the radius of a quarter of a mile if the cases were acute, and if the weather and wind were favorable; if the wind were favorable a person working within a distance of half a mile might be infected.

Dr. A. K. Chalmers, Medical Officer of Health for Glasgow, said he considered that the infective influence was felt for a mile or a mile and a quarter.

Dr. Joseph Priestley, Medical Officer of Health for Lambeth, gave similar testimony.

Dr. J. C. McVail, one of the best known British authorities upon smallpox, declared himself to hold the view that smallpox hospitals were very dangerous in disseminating the infection of smallpox to the surrounding population; the degree of danger depending upon the number of acute cases, not on the convalescents. Smallpox hospitals should be separated from populous parts by wide intervals of open ground, and it was equally important that they should not be close to traffic routes. Assuming a hospital of forty beds, Dr. McVail considered that there was really serious danger to persons within a quarter of a mile and some danger beyond that distance. In his view the danger from a hospital was due partly to aërial connection and partly to personal intercourse. With regard to risk of persons passing upon the high road, he thought that the infection might be derived from material that had been related to the hospital at one time, and in the form of dust found its way on to the high road. The evidence against the view that the infection of smallpox can be conveyed a considerable distance by means of the air was not nearly so convincing as the testimony recorded above. However, the judge found that the case in support of the theory of the aërial convection of smallpox had not been proved.

That smallpox may be conveyed by the air, according to competent authorities, has been demonstrated upon many occasions. Of course the testimony as to this mode of conveyance is by no means unanimous, but sufficient has been adduced to render the question worthy of further careful investigation. Indeed the whole subject of aërial convection of disease requires far more attentive consideration than has at present been given to it.

Cancer and Malarial Fever.

Major G. H. Fink of the British Indian Medical Service (retired) has recently issued a monograph treating of the above subject. The writer considers the various theories of cancer; the histology of the normal connective tissues, their growth, development, vascular, nervous and lymphatic supplies and the statistics relating to the malady. With regard to most of the theories of cancer, these are so well known as to need no recapitulation, besides, space is too limited to discuss but a small portion of Mr. Fink's writings. One of the most interesting features in connection with cancer dealt with by him is that which traces a resemblance between cancer and malarial fever.

The stage of malarial fever in which the "plasmodium malaria" appears in persons residing in the Tropics predisposed to the disease, thinks Mr. Fink, might be said to be analogous to the "still" condition in unicellular plant life ("Palmaglœa macrococca"), and from this "still" condition that remarkable "motile" condition arises which is seen in the life history of another humble plant, the "protococcus pluvialis," which might be said to begin in the "still" form of cell which was supposed to betoken animal life. . . . As there is conjugation in the "still" forms of plant life, and binary subdivision in the "motile" forms, so we might presumably infer, that the same occurs in the development of parasitic diseases of a fungoid, protophytic, or the protozoal and mixed forms, which invade the blood, tissues and organs, under suitable conditions; it is these stages which are not yet recognizable accurately under the microscope, since so little is yet known of the sub-kingdom "protozoa" and the class "infusoria" as well as the "mycetozoa" or protomyxomycetes" of Cunningham, and the "hæmatozoa" of Lewis.

Arguing from the fact of the changes or stages in humble plant and animal life, and that there exists a strong analogy between the disease malaria and cancer, as well as the conditions of life in tropical and temperate climates, respectively, Mr. Fink is of the opinion the conclusion must be reached that age, sex, climate and season of year, exercise and sedentary habits, as well as alcohol and food, with other habits which predispose to chronic infectious diseases, clothing, temperature, air, water, woods, locality, race, geographical, and other conditions, all enter into the question of cancerous formations and development.

The writer believes that in considering the life-history of cancer, circumstances point strongly to an analogy with malaria—the one, a disease or growth, which is creating a high mortality in temperate regions of the globe among a people living under western standards of civilization, which defer acute changes, or rather chronic infectious diseases, which set up growths. These conditions are brought about largely by climate and habits, such as the omnivorous or carnivorous indulge in; and also through flaws and defects in sanitation and hygiene which favor slow parasitic changes in the presence of alcohol, or the alcoholic habit.

The connection between malarial fever and cancer, believed in by Mr. Fink, is by no means obvious. Indeed, far more potent arguments in support of his theory must be brought forward in order to convince investigators that such is the case. With regard to the consumption of meat and of alcohol as a means of developing cancer in those predisposed to the disease, there are some grounds for the view. Several well-known medical men have propounded this theory, and a certain amount of evidence has been adduced in its support. Nevertheless, proof to this effect is lacking, the evidence having been of a negative character.

The Diminishing Birth Rate of Great Britain and What Is Involved by It.

A most pessimistic article upon this subject appeared in the *British Medical Journal*, February 20, written by Mr. J. W. Taylor, F.R.C.S., Professor of Gynecology, Birmingham University. The relatively small increase of the birth rate in Great Britain within the past few years has excited some apprehension among the thinking men of that country. A decided fall in the number of children born has ever been regarded as a sign of a country's decadence. Past history has taught this lesson with unmistakable clearness.

Mr. Taylor's address was divided into four parts. In the first part the subject for the preceding twenty-five years was considered, and it was shown that during this period the United Kingdom had sustained more loss from diminished birth rate than any other country in a corresponding lapse of time. The marriage rate was found to be rising, so that the birth loss must be due to causes operating in the married life of the population. The value of the population was found to be less than twenty years ago, and juvenile criminality, mental disease, and alcoholism were found to have greatly increased. The writer thinks that all these facts point to the following conclusions: (1) That the children born of the lower-class marriages were weak, neurotic, specially liable to alcoholism, criminality and insanity, and generally unfit for the battle of life, or (2) That marriages of the middle and better classes were now so sterile that quite an undue and dangerous proportion of the rising generation was recruited from the lower, the more ignorant, the more vicious, and semi-criminal population.

The second part of the address treats of the cause and life history of these relatively sterile marriages. Abortion was found to be the main cause. Neurasthenia was increased by the practice, and the child of the relatively sterile marriage was in every way ill-fitted to fight the battle of life, and was generally pushed to the wall by the child born of poorer but more hardy stock.

The third part of the paper is termed the prognosis of "prevention," and points to the present condition of France as exemplifying the evils of a falling birth rate.

The fourth part deals with the treatment of this national evil. The birth loss in the United Kingdom, in the opinion of Mr. Taylor, is due to causes operating in the married life of its inhabitants, and there was every reason to fear that debased ideal of married life, which was secretly and insidiously working for the ruin of the nation's power and the destruction of its hope, national decay was by no means the inevitable consequence of age—witness the history of Japan. Mr. Taylor, in conclusion, asks his countrymen to heed these warnings, and while it is yet time to mend their ways. The duty of the physician, and especially of the gynecologist, to educate the people with respect to the injurious effects of the too prevalent custom of avoiding the bearing of children, is pointed out by the writer, and an earnest plea is made to the members of the professions to do their utmost to bring about a change in the existing situation.

The Proposed Exemption of the Property of Certain Pharmaceutical Societies.

A bill to this effect has been introduced into the Senate of the State of New York. The amendment runs as follows: Property, real, from which no rent is derived, and personal property, situated within any city of the first class, and belonging to any incorporated pharmaceutical society of any county which is either wholly or partly within such city, which society has heretofore been or may hereafter be authorized and empowered by act of the Legislature to establish, and which has established or may hereafter establish, a college of pharmacy in such city, provided that such property is used for the purposes of such college and not otherwise, and provided also that the exemption of such property for any society in the counties of Kings and New York shall not exceed one hundred thousand dollars, and in any other county affected thereby, shall not exceed fifty thousand dollars.

It is difficult to say, if such an amendment as referred to above is really required or not. On the face of it, there would seem to be no adequate reason why pharmaceutical societies of the kind mentioned in the amendment should be exempt from taxation. Of course educational bodies are a necessity, and they should be dealt with as lightly as possible with regard to taxation. On the other hand the enactment of a measure freeing certain pharmaceutical societies from taxation might act as a loop-hole for the abuse of the privilege. On the whole, it may be stated that it will be better to leave matters as they are and to continue to tax pharmaceutical societies as in the past.

A Priestley Celebration.—On February 6 there was celebrated in Northumberland, Pa., the one hundredth anniversary of the death of Dr. Joseph Priestley, known for his discoveries regarding oxygen and one of the early exponents of Unitarianism in America. In 1794 Dr. Priestley was banished from England, after he had been mobbed on account of his radical religious beliefs and his house was destroyed. He came to America and settled in Northumberland. The house which Dr. Priestley built is still standing. It is a large frame structure, and adjoining it is a small building which Dr. Priestley used as his laboratory. From early manhood Dr. Priestley engaged in scientific researches, which resulted in the publishing in 1774 of a book containing the announcement of his discovery of oxygen, which he said was the result of experiments he had made with gases in a brewery near his home. He referred to the new element he had discovered as "dephlogisticated air." When he came to America he continued his experiments, but achieved no other notable results.

News of the Week.

e New Mt. Sinai Hospital was opened for in-ection on Friday and Saturday of last week, and the dication took place on Tuesday last, Governor Odell livering the address. The buildings occupy the block tending from Madison to Fifth Avenue, and from ne Hundredth to One Hundred and First Street, ten ildings in all, connected, with the exception of the lation pavilion, by corridors on the ground floor. the basement of the administration building are the itors' waiting room, dining rooms, pantries for the ident, lay, and medical staffs, and store-rooms. On first floor are the reception and examining rooms, ether with quarters for the various resident cials. On the second floor are the rooms of the ard of Directors, the committee, and the ladies' xiliary. On the third floor there is a synagogue, th a seating capacity of 200. The fifth floor is most exclusively devoted to operating rooms, the ntral one being dedicated by Benjamin Stern to e memory of his brother, Bernard Stern. It is ilt entirely of Italian marble, with the exception the floor of vitreous tile. There are two tiers seats, reached by galleries from the floor ve. On either side of the operating room rooms fitted with blanket warmers and dust-of instrument cases. In addition there is a n for sterilization. There are four additional smaller operating rooms on this floor. There is a photographic dark room and an *x*-ray room h cabinets for filing radiographs.

pidemics of Scarlet Fever and Measles.—Since middle of February there have been about forty s of scarlet fever among the children and nurses the Roman Catholic Orphan Asylum in The onx, and in other parts of the borough there are es enough reported to bring the total up to over e hundred. Over six hundred cases of measles ve also been reported within the last two weeks om the same part of the city.

The Red Cross in the East.—A branch of the Red oss Society has been established at Shanghai to st both the Japanese and Russian wounded, and relieve refugees. The Chinese have subscribed erally to the funds of the society, being much rcised over the condition of their compatriots in nchuria. It has been decided to establish a hos-al at. Newchwang. A pleasing incident is re-rted by the Tokio correspondent of the London *ndard*, who says that the kind treatment of the ssian wounded at Chemulpho is so appreciated the Russian Government that it has contributed ,000 yen to the Japanese Red Cross through the rench Minister at Seoul.

Open-air Treatment of Tuberculosis in Chicago.—n an address to a University Extension Class, Dr. illiam A. Evans of Chicago declared that if the nicipality undertakes to wage a war against this sease it can conquer it by building open shacks vacant lots in the outlying sections of the city. hese should be occupied all the year round. This ethod of treatment has been tried and has proved ccessful. Scores of Chicagoans have lived out of oors in shacks or in tents in their back yards all inter. Some of them are now in a normal condi-ion. He declared that one-sixtieth of the total pop-lation of Chicago was afflicted with tuberculosis; hat 9.4 per cent. of the deaths were caused by this isease. He said, "We hear of the lung block in New York, where, during the last nine years, in the four sides of the block, there have been 269 cases of tuberculosis. A block in Chicago beats this terrible record. In the one block in Clark Street, between Harrison and Van Buren, on the two sides of the street alone, there have been 138 cases in four years." Dr. Evans urged the importance of a daily medical inspection of lodging-houses. He quoted figures to show the appalling number of cases of tuberculosis registered at Dunning from the lodging-house districts. One hundred and fifty-nine cases at Dunning have registered from 150 numbers in Madison Street. Sixty-three cases have registered from one block in South State Street; 25 cases have registered from 449 Clark Street alone; 15 cases from 90 Van Buren Street, and 17 cases from 103 Desplaines Street.

Cincinnati Academy of Medicine.—At a business meeting of the Academy, held March 7, the following officers were elected for the coming year: *President*, Dr. S. P. Kramer; *First Vice-President*, Dr. J. M. Withrow; *Second Vice-President*, Dr. Julia Carpenter; *Secretary*, Dr. Stephen E. Cone; *Treasurer*, Dr. Magnus Tate; *Librarian*, Dr. Arch J. Carson; *Trustees for terms of three years*, Drs. James F. Heady and David I. Wolfstein. Dr. Byron Stanton, the retiring president, gave a valedictory address. A resolution of approval was passed for the appointment of a commission to build a State sanatorium for incipient phthisis.

Jewish Doctors Sent to the Front.—Some curious particulars are given in a dispatch to the *New York Times* regarding the workings of official anti-Semitism in Russia. M. de Plehve, who insisted upon revising the lists of reservists called out, has sent an enormous percentage of Jews to the front, including most of the doctors of that race in St. Petersburg. Out of 180 medical men who left at the beginning of the month 110 were Jews. Two reasons were given for this action. One reason was that the Hebrew savants are all supposed to be Liberals, whose presence in Russia at critical times is considered undesirable. The other alleged reason was that influences were brought to bear on behalf of certain non-Jewish practitioners, who were only too glad to get their rivals out of the way. The Jewish doctors sent to the East are deprived of part of their emoluments, and receive only 900 rubles ($450) for traveling expenses, whereas Christians get 1,250 rubles.

Failure of Schmidt's Cancer Serum.—Nine patients suffering from cancer have been treated at the Middlesex Hospital, London, by Dr. H. Jossé Johnson since November 26, 1903. Concerning these cases, the members of the committee on cancer investigation report in *The Lancet* of March 5 that they have failed to observe any trace of a specific local or general reaction to the injections, and are therefore convinced that the material is entirely without diagnostic value. They have equally failed to see any local or general improvement in the condition of a patient. The injections in no wise altered the course of the disease. In the case of those patients who died microscopical examination of the tissues failed to reveal any differences in appearance from those usually met with in cases that have not undergone the special treatment. The material used was sent direct from Dr. Schmidt's laboratory to Dr. Johnson and Dr. Johnson, made all the injections himself, except on two occasions. The material used was Dr. Schmidt's "killed culture."

Dr. William S. Halsted of Johns Hopkins University will be the orator at the annual commencement exercises of the Yale Medical School, to be held on Monday, June 27. His subject is not announced, but will be some topic connected with modern surgery. Dr. Halsted was graduated from the Yale Academic department in the class of '74, from the Columbia Medical School in '77.

New Professors at Columbia.—Dr. Gorham Bacon has been appointed clinical professor of otology at the College of Physicians and Surgeons to succeed *Prof.* Albert H. Buck, and Dr. William Kelly Simpson, clinical professor of laryngology, to succeed *Prof.* George M. Lefferts. Dr. Edwin B. Cragin has been made professor of gynecology, and Dr. H. M. Painter clinical professor of obstetrics.

Successful Treatment of Tetanus.—The newspapers of this city have noted recently the recovery from tetanus of a Brooklyn boy after the injection of antitoxin into the spinal sheath. This method was first practised, we believe, by von Leyden in 1901, and five cases with three recoveries were reported in the *Journal of the American Medical Association*, in 1902. In another column of this issue is a report from *The Lancet* of March 5, of four cases with three recoveries. This is a much more simple method than trephining the skull in order to make intracerebral injections and appears to be equally efficacious.

Exclusion of Mentally Defective Immigrants.—A State board of expert sanity inspectors, to be stationed at Ellis Island, to inspect immigrants as they land, with a view of detecting those in such stages of mental decline as would lead to their becoming a public charge, is provided for in a bill introduced last week at Albany in behalf of the State Commission in Lunacy. Although there is a question as to the jurisdiction of the State of New York over the matter of immigration, it is said that the United States Commissioner of Immigration is in favor of the proposition, and that the necessary permission would be instantly granted by the Government.

A New Ordinance for Hospitals.—At a recent meeting of representatives of the various hospitals of Chicago, there was a discussion on suggested changes in the city hospital ordinance, which is said to be so defective that, were it enforced, no hospital could operate under its provisions. A sub-committee was appointed to draft a new ordinance. This committee consists of Drs. D. A. K. Steele of the Chicago Hospital, L. Blake Baldwin of the Samaritan Hospital, A. J. Ochsner of Augustana Hospital, J. H. Hoelscher of Alexian Brothers' Hospital, and M. L. Harris of the Passavant Memorial Hospital.

The Henry Phipps Institute Lectures.—The fifth lecture in the International Course given under the auspices of the Phipps Institute will be delivered by Professor C. Maragliano of Genoa, Italy, on Monday evening, March 28, at the Witherspoon Building, Philadelphia. The subject of the lecture will be "The Specific Therapy of Tuberculosis and Vaccination against the Disease."

Christ's Hospital Reopened.—A formal reopening of Christ's Hospital, Cincinnati, took place on March 10. The hospital has been closed for some months while additions and improvements to the extent of $100,000 were made. The opening was attended by a large number of visitors.

A Toy Pistol Ordinance.—The Cincinnati council passed an ordinance March 7 prohibiting the sale of toy-pistols, caps, and blank cartridges to minors, fixing the penalty at $100. This measure was urged by the Academy of Medicine some time ago as a means to the prevention of tetanus.

Hospitals in Financial Difficulties.—As a result of lack of funds, the female surgical ward of Roosevelt Hospital has been closed. This makes the third ward to be closed in large hospitals in this city within a short time. The New York Hospital was compelled to close a ward, and recently the Manhattan Eye and Ear Infirmary closed a pavilion on account of lack of funds. The female surgical ward co tained twenty-eight beds. In place of this wa hereafter twelve beds in a small ward, which h been the convalescent male surgical ward, will used. The convalescent male surgical ward has be abolished.

Free Antitoxin in Chicago.—The Chicago He Department has announced that physicians m obtain antitoxin free from the antitoxin stations the Department for the gratuitous treatment their charity cases. Physicians may also have th prescriptions for antitoxin to be used in their p practice filled by any antitoxin station at fi prices. The physician obtaining free antito receipts for it, and the receipt contains the follow certificate: "I hereby certify that the family of patient is unable to pay for the antitoxin; that case is urgent; that I am attending without fee, that I will report the termination of the case on postal card form of the Health Department furnis by the druggist."

Victims of the Chicago Theater Fire.—Accord to the Coroner's records in Chicago, the numbe persons who perished in the fire in the Iroq Theater and those who have died from the effe of injuries then received is 576.

Fee for Report of Contagious Diseases.—The Bo of Health of Passaic, N. J., announces that in fut physicians of that place will be paid a fee of cents for each case of contagious disease reported them. The board also wishes to keep track of cases of consumption in the city, and has as the health physicians to aid in this work. This started some years ago, but the physicians gave reporting the cases because inspectors visited houses of those ill and made their presence noxious.

The College of Pharmacy has just been mad school of Columbia University, the management the college being under the direction of the univer council.

A Hospital Burned.—The City Hospital at Melr Mass., burned early last Saturday morning. patients were all saved, though with the grea difficulty, by the nurses.

Obituary Notes.—Dr. HENRY ALBERT RUNDL of this city died on March 9 of pneumonia at the of forty-eight years. He was a graduate of the H vard Medical School in the class of 1887.

Dr. VERRANUS MORSE died at his home in Bro lyn on March 9, aged eighty-five years. The caus death was shock following fracture of the hip. was born in Springfield, N. H., in 1818, graduat from Dartmouth College in 1845, and from the me cal department of the New York University in 18 when he took up the practice of medicine in city. Dr. Morse was one of the founders of Young Men's Christian Association in New York Ci and was for some years treasurer and a director the association.

Dr. WILLIAM J. MCDERMOTT of this city died March 12 after a long illness, at the age of seven three years. He was born in Portland, Me., a received his early education in St. John, N. B. 1854 he was graduated in medicine, and after t years of study in Europe he began practice in We chester. Dr. McDermott was elected to the A sembly in 1860, but when the first call for troo was issued he resigned from the Assembly and e listed as surgeon and went to the front with th Sixth New York Volunteers. He saw much activ service. He was with Colonel Ellsworth when that officer was shot at Alexandria, and ran to his assist

e. He assisted in the amputation of General ward's arm at the battle of Fair Oaks, and participated in the battle of the Wilderness, being left harge of the wounded. He was captured and to Libby Prison, where, after a short term, was paroled. He was mustered out of the rice in October, 1865, and then resumed his practin Westchester.

r. STANLEY G. CLARKE of Brooklyn died on ch 5 at his home in that city from disease he heart. He was born in Camden, Ont., in and was graduated from the New York Uniity Medical School in the class of 1868. He n the practice of medicine in Brooklyn about n years ago. He was one of the organizers e Central Throat Hospital, and had been presit of its board of managers. He was a member he Medical Society of the County of Kings of the Brooklyn Medical Society, and had been nspector of the Board of Health in Brooklyn everal years.

r. MIDDLETON STUART HANCKEL, a retired ician, died on March 12 at his home in this city. was born in Charleston, S. C., on April 17, 1828. was graduated from the Charleston Medical Col-. He had been in this city for the last nine s, but had never practised here.

r. CHARLES H. RICHMOND, one of the best-known titioners of Western New York, died at his e in Livonia, Livingston Co., on March 2, sixty-three years. Dr. Richmond went to the War as a surgeon soon after graduating from Buffalo Medical College in 1860. He was at the of death connected with his alma mater as tor. He was also a member of the Livingston nty Medical Society and of the New York State iety.

Dr. JOHN P. EDGE died at Downingtown, Pa., on rch 7 at the age of eighty-one years. He was duated from Jefferson Medical College in the class 1846 and was a representative in the Pennsylia Legislatures during the sessions of 1875, 1876, 7, 1878. He was the originator of the bill blishing the Board of Agriculture, and he was a number of years a member of the board.

Dr. ROBERT MCKINLEY, a native of Scotland and ident of Santa Barbara since 1894, died on Febru- 28, at the age of forty-three years.

Dr. L. D. SCHERER died at Los Angeles on March his fifty-seventh year. After having apparently ained his health, Dr. Scherer had in a few years ilt up a large local practice, and his death is atbuted chiefly to overwork.

Dr. PHILIP D. CARPER died at Los Angeles on rch 4, aged forty-one years. He was a native Colfax, Iowa, and, after graduation from the a State University, practised for a time at icago. Later he went to the Klondike and enged in practice at Dawson, with enough spare e to discover some valuable mines.

Puerperal Septic Infection.—In Caruso's alcoholic irrigation method, two rubber tubes are introduced into the uterus with loose gauze packing. Every four hours eight ounces of alcohol are injected through one tube and allowed to escape through the other—40 to 80 per cent. alcohol is employed. Results not superior to those of semi-expectant treatment. Fochier injects early in the attack 1 c.c. of sterilized essence of turpentine into the cellular tissue of the deltoid region or the flank. The resulting abscesses are opened and drained. Cheron and others report subsidence of the febrile symptoms. Webster packs the uterus with a pint of sterile water containing four ounces of glycerin, and 30 m. of formalin.—CHARLES JEWETT, in *Brooklyn Medical Journal*.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INSTITUTE OF MEDICAL SCIENCES—HOSPITAL MEETINGS—AMALGAMATION—FINANCE—CANCER—ARTERIAL SCLEROSIS—PRESCRIBING AND DIGNITY—DRS. JAMESON AND SMARTT—SIR S. WILKS—DEATH OF SIR E. SIEVEKING.

LONDON, February 26, 1904.

THE Institute of the Medical Sciences, under the direction of The University of London, promises to become an accomplished fact. The King has subscribed 100 guineas toward the fund being raised, and expressed great interest in the scheme. The presidents of the two colleges subscribe similar sums. Mr. Alfred Beit has given £5,000 and Messrs. Rothschild £500.

Quite a number of hospitals are holding their annual meetings, and at all the plea is for more money. Many of these appeals will meet with a good reception; but the pressure on the public has of late been so extreme that others may well regard the future with forebodings. Amalgamation is still talked about, but the progress it makes is slow, so many interests having to be considered.

In a former letter I explained the position of the Royal Ophthalmic Hospital and its financial prospects. These have not yet improved, and the chairman of the meeting this week gave some further details, but the chief event was the desire of the M. P. for the district, who said he had several millionaires in his constituency, but none had come to the rescue of this great charity.

The Central Ophthalmic had its annual meeting yesterday. The suggestion made by the King's Fund Committee to amalgamate with the Royal Free Hospital did not commend itself to the chairman, who held that there are various reasons why special hospitals should be separate from the general hospitals. In this case, though, the saving would only be £50 per annum in expenses.

King's also had its annual meeting yesterday, when Lord Methuen presided. The approaching removal was necessarily referred to in the report and speeches, but I have given you full particulars respecting it.

Charing Cross had its meeting on Wednesday, and the financial state is not satisfactory. A loan of £85,000 is being negotiated. Nearly $50,000 is required to complete the new buildings and furnish. It really looks as if the extravagance of hospital managers ought to be in some way checked. They are all for building and extending.

The Middlesex Hospital meeting was also yesterday, and its report contained interesting details of the research work on cancer at that institution. During the year 100 cases were treated with *x*-rays, and the results are reported to be encouraging. Pain has been relieved and in a number of cases the disease has been retarded, and in some undergone retrogressive changes. Dr. Otto Schmidt's treatment was tried with negative results. The work at the Middlesex, both bacteriological and clinical, is of the highest order.

At the Cancer Hospital's meeting on Wednesday the senior surgeon (Dr. H. Snow) addressed the governors on the work of the institution, and claimed that "nowhere else in the world" had the disease been studied as it had been at this hospital. He wanted the schemes of cancer research to be all coördinated and correlated. To this end he proposed a world's congress on the disease. Until this proposal is adopted, he thinks cancer will remain "the darkest Africa on the map of medicine."

The newspapers continue to show their interest in cancer—sometimes in a manner to be deprecated. One of them publishes a telegram to the effect that Dr. Doyen of Paris claims that cancer is no longer to be called an incurable disease, as out of 126 cases treated by him, twenty-one now show no sign of the disease, and forty-seven are improved. He admits, strange to say, that fifty-eight gave no favorable result from his treatment, consisting in injections prepared from "the microbe known as *Micrococcus neoformans*, peculiar to cancerous tumors."

Another newspaper has accepted an advertisement offering to sell a cancer cure for 1,000 guineas. Alas for the gullibility of the public and the infamy of quacks!

A discussion on arterial sclerosis was opened at the Pathological Society on the 16th inst., by Dr. Savill readreading a paper on hypermyotrophy and other morbid changes in the muscular tunic of the arteries. He defined arterial sclerosis as a chronic, generalized, thickening, condensation or degeneration of the arterial walls, which were found hard, or less elastic than normal, the lumen remaining unduly patent after death. He gave details of thirty cases which had presented circulatory symptoms during life and characteristic appearances after death. The muscular coat he regarded as the proper tissue of the arterial system, and on its performing its function the healthy action of the cardiovascular and other systems

depended. To show the pathological importance of the muscular coat, Dr. Savill described the case of a woman who died at the age of one hundred and exhibited sections of her organs. He concludes that extensive patchy atheroma is consistent with great longevity and absence of symptoms or vascular complications, and the same may be said of generalized sclerosis, so long as the tunica media is relatively free from disease. He grouped the morbid changes in the muscular coat as follows: (1) Atrophy, not common. (2) Hypertrophy, not uncommon after middle life. (3) Cloudy swelling not always revealed by ordinary stains, but easily demonstrated by acid orcein. (4) Granular degeneration, often associated with cloudy swelling. All these four changes have a generalized distribution in the arterial system, though often more marked in one area than another, *e.g.* in the lower extremities. (5) Necrosis. (6) Calcification. "Arterial hypermyotrophy" is a term applied by Dr. Savill as long ago as 1891, and he regards the condition as primarily a true hypertrophy, just as the term is used of thickening of the cardiac walls. That degeneration may have set in before the case reaches the post-mortem room does not disprove the existence of hypertrophy. Clinically, he says the disease constitutes a distinct pathological condition of prolonged course, capable of recognition during life by careful investigation, sometimes, but not always, associated with renal disease, and being, in fact, one of the chief conditions on which cerebral and other hemorrhages depend. Of his thirty cases seventeen were relatively uncomplicated by other arterial disease and represented the earlier stages. In only nine was there renal disease, the other twenty-one presenting no renal change during life, and no evidence of kidney disease after death. Cardiac hypertrophy was present in twenty-eight of the thirty cases. High blood-pressure was observed in all cases seen before the final stage, and among the consequences of the disease, which resemble those of high tension, the most serious is cerebral hemorrhage. Moreover, hemorrhages occurred in other situations in spite of the thickened arteries.

Professor Clifford Allbutt recognized three forms of arteriosclerosis : (1) Toxic, as from lead, syphilis, diabetes; (2) Involutionary, as senile decay, which may appear before seventy; (3) Secondary, when the muscular coat of the artery is hypertrophied. The discussion mainly turned on this, and Dr. Allbutt held the first factor to be rise of arterial pressure, the disease being a mechanical consequence of the hyperpiesis instead of the converse. In turn, this factor depending on some alteration of the blood, and this, in its turn, on perverted metabolism; the cause, he thought, sedentary life and high feeding. It occurred in the strictly temperate, but he believed most cases were due to repletion, relative or positive.

Dr. J. Broadbent said atheroma must be included under arteriosclerosis, it being scarcely possible to consider them separately. In sixteen cases of cerebral hemorrhage, one of the most common accidents in arteriosclerosis, there was senile degeneration in two (both over eighty); the other fourteen were connected with the kidney. In all the fourteen, the heart and middle coat of the radial were greatly hypertrophied without signs of degeneration. In four cases there was advanced atheroma of the aorta, and in the others, slight changes.

Dr. Parkes Weber thought that mostly arterial hypermyotrophy was compensatory, though there were apparent exceptions in cases of nervous origin, such as the cardiac hypertrophy sometimes met with in tachycardia without valvular disease, some cases of Graves' disease and the arterial cases in limbs affected by conditions allied to erythromelalgia or Raynaud's symptom-complex. Extreme increase of corpuscles might also render the circulation through the arterioles more difficult.

Dr. Pavy said the two chief factors were a toxic agent and renal disease. Cases occurred with the characteristics of Bright's disease, but in which neither albumin nor casts were found. In one mentioned these appeared some years later. The cardiovascular symptoms preceded the renal affection. Probably defective metabolism gave rise to a toxin which produced the vascular change. It was, he thought, important to diminish the quantity of nitrogenous food in such cases.

Those who hold that to forbid doctors to dispense their prescriptions, on the pretense that the dignity of the profession would be increased, and that it is at a higher level where such law exists, may take this as an object lesson. In the Department of the Gard the authorities fixed the fee for public vaccinators at five centimes a case, to include the visit for inspection on the eighth day. The doctors are declining to work for this munificent fee, but the proposal shows that the public estimate of professional services is not raised when dispensing is forbidden.

Now that a doctor has become Premier of the Cape, and has associated another doctor in his cabinet, you may like to hear what we are saying about them.

Dr. Jameson's name has so long been known in connection with the raid that many people forget his other claims to notice. He proved himself a level-headed administrator in Rhodesia. He organized the Matabele War in a manner which our War Office might well have imitated. He took his M.D., Lond., in 1877, and went to South Africa on account of threatened phthisis, and practised at Kimberley until his appointment in Rhodesia by Mr. Rhodes, who had unbounded faith in his abilities. He was in Ladysmith during the siege, and suffered from typhoid fever. Yet this man of weak body but strong mind survives and is as active as ever. He is a man of few words, of great coolness, and under fire will quietly smoke a cigarette as if in contempt of bullets.

Dr. Smartt, who also abandoned the profession for Colonial politics, is an Irishman by birth, and like many of his countrymen who take to public life, a fluent speaker. He is not new to office, having been a secretary in Sir Gordon Sprigg's cabinet in 1898. He is the owner of much land in the colony, and has a great experience of irrigation.

I regret to report that Sir Samuel Wilks is worse, and the anxiety of his friends very great.

Another of our leaders—one of the most esteemed—passed from among us on Wednesday in his eighty-eighth year. Full of days and full of honors, Sir Edward Sieveking is gathered, like a shock of corn in its season, fully ripe. He took his M.D., Edin., as long ago as 1841. In 1852 he became a Fellow of the Royal College of Physicians, in which he has filled, during his long career, nearly every office. He had previously edited Rokitansky's Pathological Anatomy, and in 1853 he brought out Romberg's Nervous Diseases. The next year he published jointly with the late Dr. Handfield Jones a "Manual of Pathological Anatomy," which you must remember, for it held the first place as a textbook of the subject for many years. He was for the full period physician to St. Mary's Hospital and then consulting physician. This office he also held at the Lock Hospital. For a long time he was physician to the Hospital for the Paralyzed and Epileptic. This reminds me of his book "On Epilepsy and Epileptiform Seizures," which reached a second edition in 1861, and his Croonian Lectures on "Localization in Disease," 1866. He had been president of the Medical and Chirurgical, Harveian and Balnological Societies, and held many other distinctions showing the esteem of his brethren. For some years he edited the *British and Foreign Medico-Chirurgical Review*, now discontinued, as the quarterly issue seems unable to satisfy readers with early information, and the erudite articles of the race of quarterly reviewers have to be divided into instalments.

Sir Edward Sieveking was, I believe, the Aesthesiometer. Other claims to distinction might be named, but none, perhaps, greater than the way in which in all his career he maintained the honor of his profession. He was physician to the late Queen (until her decease), by whom he was knighted, and to the Prince of Wales, from 1863 until he became King, when he was made Physician Extraordinary to His Majesty. He also had the jubilee medal of 1887, and the clasp of Queen Victoria's diamond jubilee.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CASUALTIES FROM EXPLOSIONS—DEADLY GAS GIVEN OFF BY COPRA—CARE OF THE INSANE—BERIBERI AND SCURVY IN A JAIL—PROTECTION FROM MALARIA—SANITATION IN THE MORO PROVINCES—ANIMAL DISEASES.

MANILA, January 25, 1904.

A SERIES of casualties from noxious and explosive gases has lately occurred in the islands, several of which were of much interest from a medicolegal aspect. All occurred in the space of about a month. The first accident occurred following a blast in the quarries at Mariveles, where large quantities of rock are being procured for the improvement of the port of Manila. In this blast some forty-three tons of explosives were used, including dynamite, black blasting powder, Hudson powder and some thirty-two tons of condemned Spanish ordnance powder, captured at the fall of the city. This powder was all exploded in one blast at Mariveles. After the smoke had cleared away, some twenty minutes after the explosion, the experienced American quarrymen, followed by natives, picked their way over the fallen rocks, which extended down to the water's edge of Mariveles Bay. After passing practically over the scene of the explosion, the American in the lead was seen to fall unconscious. Others, Americans and natives, hastened to his assistance, when they, too, were overcome, without warning, and fell. The remaining Filipinos then made their way to safety, while the Ameri-

ans, some of whom were in boats about to land, made very effort to remove the unconscious victims of the gas om the dangerous zone, though fully aware that they ere going to probable death themselves. These bodies ere finally removed. In all, about a score of persons ere seriously affected, and of these eight died, four being mericans. The effect of the gas was immediate, unnsciousness occurring instantaneously, and the victims lling with such suddenness and force as, in two cases, to sh in their skulls against the jagged rocks. Those mediately removed, rapidly recovered, but those exed to the gas more than a few minutes remained uncons for from two to thirty-six hours. The gas, or xture of gases, producing the above effects, was probly carbon monoxide, which is known to be a prominent composition product of the powders used. An impornt feature of this accident was that it occurred on an en shore of a promontory, on a sloping level well above waters edge and wind-swept at the time by a stormy eeze twenty minutes to half an hour after the blast had curred, and when the dissipation of noxious gases ght fairly have been anticipated.

Several days after the above accident an ammonia plosion occurred on an army transport at Zambranga, which a number of persons were killed or wounded.

Shortly after the second accident, a vessel put into nila Bay with a cargo of copra, held under battened tches for three days. After some delay, following moval of these hatches, three Filipinos went down to in removal of the cargo. All at once fell unconscious. American started below to save them, when he, too, ame unconscious, and was pulled to the deck with fficulty. A few breaths of fresh air revived him, and he rted to go below again, but the Filipinos held him back stood idly by for an hour without making any effort sist their friends. Finally, at the end of an hour, the dies of the latter were removed dead. It is stated that ra gives off carbon dioxide in its decomposition, which uld have been facilitated by the heat and moisture of the ed hold. However, vessels are constantly carrying ra under the same conditions, and no accident of this has been previously reported. At the time the dead dies were removed, a strong odor, similar to that of trite of amyl, is said to have been noticeable below tks.

The fourth accident occurred several days later on the rd of health steam scavenger barge, which carries out sea and dumps the excretal refuse of the city. This sel has sixteen compartments for excreta, each ventted by a flue passing from the top of the compartnt into the smoke stack, the heat in the latter aspirating the air of the excreta compartments and burning the ses. After dumping a compartment by elevating a plug the bottom, the compartment is washed down with hose d then workmen descend therein to remove a small ount of solid remainder, like sticks and stones, which not escape through the opening in the bottom. One lor had thus descended and another was passing a ntern down to him when the gas in the compartment ploded, burning both severely. This gas was probably rsh gas. It was thought that the accident was due to lure on the part of the aspirating apparatus to work operly, but three days later a lantern was held three or ur feet above the open manhole of a compartment hich had been dumped some time before, when a second plosion occurred, which shook the ship and seriously rned the native holding the lantern. To prevent rther accident, electric lights were at once installed on e vessel.

The Board of Health has lately given much attention to roviding accommodations for the insane, the proposition solving itself into the provision of temporary accommotions to meet immediate pressing necessities in the icinity of Manila, and the erection of modern permanent stitutions to care ultimately for all the insane throughout e islands. At present the only asylum in Manila is uch overcrowded, and it has been necessary to send a ertain number of insane to Bilibid for temporary safe keeping. It was hoped that in the recent sale of friar lands the convent and ground at San Felipe Neri, near Manila, would be available for immediate temporary needs and provide accommodation for some three hundred insane, perhaps serving also as a nucleus for a permanent institution, but at the last moment the sale of this property fell through. Now it is proposed to establish a hospital for about one hundred insane in the hacienda of Lolomboy, on the friar rice lands, about fourteen miles up the railroad north of Manila. In the meantime a census of the insane throughout the islands is being taken, and the returns so far received indicate that there are about 3,500 insane in the islands who will require to be provided for in institutions to be maintained by the Government.

A very interesting condition has been found to exist in the provincial jail of Albay province, in the simultaneous occurrence of both beriberi and scurvy. A certain amount of beriberi is practically to be expected where a large number of Asiatics are closely confined, and in the Albay jail a considerable mortality occurred from this disease. A certain number of cases presented, however, indefinite symptoms, which did not yield to treatment. The native physician was ordered away and replaced by an American doctor, who found, on arrival, a number of well-marked cases of scurvy, some of which were resulting fatally. With the isolation of the beriberi cases and the placing of the remainder of the prisoners on an antiscorbutic treatment, prompt improvement of the situation resulted. Scurvy being practically unknown, among the ordinary native class, which largely subsist on fresh fruits and vegetables, it was not strange that this disease was unrecognized by the Filipino doctor formerly in charge. The outbreak of scurvy in the Albay jail indicates that hereafter this disease must be recorded as among the possibilities in public institutions in the Philippine Islands as elsewhere.

The military authorities have lately given special attention to bringing about reduction in the sick report from malarial disease. General orders have been issued on this matter covering the matter of mosquito destruction and prevention, the protection of troops against the mosquito and the treatment of malarial cases under conditions preventing the conveyance of their infection to others. A number of the more malarial posts have been abandoned, and a systematic study of the mosquito life in the vicinity of the army posts is being carried out. Sick reports are scrutinized for malarial cases, and any undue proportion is a cause for explanation. Blood examinations are required in respect to all cases presenting temperature. All this is having an excellent effect, but unfortunately all precautionary measures are not easily carried out in certain posts, particularly those on low-lying sites which are not readily drained, or the surface pools of which it is difficult to keep properly oiled. Destruction of mature mosquitos in the open type of barrack or building most comfortable in the islands is also far from easy, as they are so open that it is difficult to get a sufficient concentration of sulphur fumes or pyrethrum smudge seriously to affect the insects. However, every effort has a certain effect in the desired direction, and the imperfections of a system are no reason for its condemnation as a whole. The results, so far, are very encouraging.

The sanitary organization of the newly conquered Moro provinces is being perfected by General Wood, who is much interested in such matters. These provinces are under military control, though certain military officials have civil functions, and there are also a few civil officials among the governing authorities. The present plan of sanitary organization is based on that in existence in other parts of the islands, with slight modifications necessarily dependent upon local conditions. There being no local physicians, the health work will naturally fall to the army surgeons. There will be an army surgeon detailed as provincial health officer, and other army surgeons, in addition to their other duties, will act as municipal and district health officers. Hospital sergeants and privates will act as sanitary agents, inspectors, police, and vaccinators. Vaccination work will be pushed as rapidly as possible, as smallpox is very rife among the Moros, few of whom have been vaccinated. As the Moro towns are not large, only a few elementary sanitary rules need be enforced at the outset. The military sanitary organization, while given a free hand, will practically coöperate with the Board of Health for the archipelago, using the same methods and report forms, so that the statistics created may be available for consolidation with those from the provinces under civil rule to form returns for the entire islands. It is proposed to establish and operate several hospitals, since medical treatment, aside from motives of humanity, has been found to be a potent agent in winning the confidence of the Moros.

Animal diseases are giving much concern at the present time. Hemorrhagic septicæmia was several times lately imported in animals brought from China, but was fortunately early detected and stamped out in each instance. Rinderpest has killed many bovines, but the few remaining animals appear to be largely immune, and where the disease develops it is readily controlled by prompt inoculation. Localized outbreaks of anthrax and foot-and-mouth disease have lately occurred in various provinces, but these have been prevented from spreading and assuming a seriously epidemic character. Glanders is widespread and destroys a large number of animals. As with other epidemic diseases, the infection is often kept up by the unwillingness of the native to destroy his diseased animal, and except in a few districts there is no law compelling such destruction. Surra is committing

ravages, appears to be rapidly spreading, and has already established itself in many widely separated districts of the islands. It is now proven to be a potent cause of death among carabao, which animal was until recently supposed to be immune to the disease. The government has imported some thousands of carabao from China for the purpose of restocking the islands in the promotion of agriculture, and these China carabao appear to be especially susceptible to this disease, whether from a natural lack of resistance or due to their enfeebled condition resulting from the vicissitudes of a sea voyage and the protective inoculation against rinderpest, to which they have been subjected on arrival. Several of the various herds imported have become infected with surra and have been utterly destroyed by this disease, in spite of every effort. Experience has shown that with such an imported herd once infected, it is a saving of time and money to at once destroy the whole herd, even though but one or two animals may show the infection. With one herd in particular, a veterinarian was constantly in attendance, blood examination of stained specimens from each animal was made almost daily, and any animal presenting evidence of the disease was forthwith removed and destroyed. Nevertheless, the disease continued to develop in the remainder of the herd, although this was moved to several localities, until the last animal had been, in the course of a couple of months, destroyed. So far, no remedy has been found which has the least effect upon the progress of the disease, and the only apparent available measures for coping with it appear to lie in splitting up the herds into small groups and destroying diseased animals without delay. Surra in carabao is far less acute in its course than in horses, which usually die in a few weeks. Carabao, however, may harbor the parasite for months without presenting clinical symptoms, and be a constant source of infection to others. Carabao may live six or eight months with the disease, the microscope revealing the parasite from time to time only at certain cyclic stages of its development. On examination the animal may thus appear to be healthy, and the blood reveal no parasite, at a time when it is itself doomed and an almost certain source of infection to others.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 25, 1904.

A Comparison between the Medical Uses of the X-rays and the Rays from the Salts of Radium.—Francis H. Willikins presents this brief summary of his paper: (1) The rays from radium salts, unlike the *x*-rays, are not serviceable in diagnosis, either by means of radiographs or of fluoroscopic examinations. (2) The Beta rays are useful as a therapeutic agent in certain skin diseases and new growths, if the diseased tissues are superficial or are not more than about 1.25 cm. (one-half an inch) below the surface of the skin or accessible mucous membranes. (3) The Beta rays from radium salts will heal some cases of new growths that are not healed by the *x*-rays, and they act more promptly, but not over so large a surface at one time as the *x*-rays. (4) Radium salts of an activity of 8,000, or considerably more, are not sufficiently strong to be efficient. Pure radium salts which have a radioactivity of about 1,500,000 are not too strong for the work to be done. (5) The radiation from radium salts, unlike that from the *x*-ray tube, is uniform. (6) Great care should be exercised to avoid burns.

The Prognosis of Idiopathic Pleurisy.—George G. Sears has made a study of 439 cases of pleurisy which were treated between the years 1880 and 1895. These cases include those only in which no suspicion arose that the acute attack was a secondary manifestation of some process already existing. The possibility of a previous tuberculosis excluded a case from this series. Neither were any cases included which appeared in the course of pneumonia, typhoid fever, or other acute disease. These cases are grouped together as instances of acute, idiopathic pleurisy, without regard to their possible etiology. They have been studied with the purpose of determining whether they throw any light on the question of prognosis. The only conclusions which the study of this series justifies are: That about 10 per cent. of these cases are known to have developed tuberculosis; that over 55 per cent. of all cases which were followed to their death had died from some form of tuberculosis; that tuberculosis when it occurred developed within five years in over 50 per cent., and within ten years in over 70 per cent.; that this danger is much increased by a tuberculous family history or a personal history of some form of tuberculosis previous to the attack.

Journal of the American Medical Association, March 12, 1904.

The Value of an Injury.—L. Sexton summarizes the recent legal decisions rendered in cases, of persons who had sued railroad and other corporations for injuries received in the line of duty. He notes that the highest verdict which is reported to have been set aside was that in favor of an English physician against a railroad. The plaintiff was awarded £7,000, but the Court decided this sum inadequate, as the physician was in the prime of life, having a practice worth, perhaps, the sum named annually, and was reduced to a condition of helplessness, with every enjoyment of life destroyed, and with the prospect of a speedy death.

Abdominal Pain and Pneumonia.—G. H. Scott reports the case of a girl of twenty years whose first symptom was severe umbilical pain, radiating from this point downward and laterally. At first, it was sharp, but later, merely a dull ache. There was a moderate febrile movement and a few râles heard in the chest. The next day the symptoms present were those of an acute bronchitis. The condition gradually became aggravated, and on the fourth day of the illness, though the abdominal symptoms had subsided, it was possible to make out an acute lobar pneumonia of the right upper lobe. At this point the patient complained for the first time of pain and constriction in the chest, but, curiously enough, on the left side, which was normal. The patient then ran a typical course of pneumonia, the temperature falling by crisis on the twelfth day after the original onset of illness. On the second day of the pneumonic process the abdominal pain returned, and continued in a slight degree during the entire course of the disease, subsiding entirely at the crisis, never to recur. There were no other abdominal symptoms nor any abdominal signs. Convalescence was rapid and perfect. Four weeks later an acute beriberi developed (the woman lived in the Philippines), and death occurred eighteen days later.

The Condition of the Blood in Patients Suffering from Pulmonary Tuberculosis.—The paper of J. M. Swan is the result of a study of twenty-five cases of the disease, and discusses the question in great detail. The author's conclusions may be summarized as follows: (1) The blood picture in pulmonary tuberculosis is by no means constant. (2) The average case in the first stage of the disease presents a slightly reduced number of erythrocytes, a moderate reduction of the hæmoglobin, and about a normal number of leucocytes. The average case in the second stage presents a varying degree of leucocytosis, due to an increase in the number of polymorphonuclear, neutrophile cells. The erythrocytes are present in about normal numbers and the hæmoglobin is often normal in percentage. The average cases in the third stage will show a reduction in the number of erythrocytes, a moderate leucocytosis composed of the polymorphonuclear, neutrophile sells and a high hæmoglobin percentage. (3) Hemorrhage is usually followed by a marked reduction in hæmoglobin, a slight reduction in the number of erythrocytes. Leucocytosis is not an invariable feature of a post-hemorrhagic blood. (4) Albuminuria of itself appears to cause no constant change in the blood picture. (5) Tuberculous diarrhœa is apparently attended by a reduction of the number of the erythrocytes and of the percentage of hæmoglobin, and by an increase of the leucocytes. The latter increase is due to the polymorphonuclear, neutrophile cells. (6) Pleurisy is usually accompanied by a polymorphonuclear, neutrophile leucocytosis. (7) There is no distinctive blood picture that will serve to differentiate between extensive cavity formation due to tuberculous degeneration and that due to other causes. Further, leucocytosis is not a constant feature of cavity formation. (8) The leucocytosis occurring in the course of pulmonary tuberculosis is due to an increase of the polymorphonuclear elements, and not to an increase of the lymphocytes or of the transitional cells. (9) The absence of the eosinophile sell from the blood may be looked on as an unfavorable prognostic sign. The increase of these cells while the patient is under treatment may be taken as an indication that the progress of the disease has a tendency to become arrested.

Medical News, March 12, 1904.

A Factor in the Etiology of Distorted Nasal Septa.—Chas. E. Quimby believes that children with irregular teeth, high palatine, or narrow alveolar arch and distorted nasal septum should be treated by the dentist and rhinologist together. The work cannot be done after ossification at the line of maxillary union is well advanced; or after puberty. Still, before this time the teeth are seldom sufficiently developed to make a satisfactory final regulation if they are of the triangular variety. So the earlier work should be directed specially to the correction of the nasal defect and the final regulation of the teeth left for some years later. The writer reports a case in point in which the sequence of events was as follows: Development of mouth-breathing coincident with an exceedingly irregular second dentition following perfect respiration in early life; the discovery of a deflected septum nearly closing the right nostril; almost complete disappearance of the septa

xion, a subjective appreciation of freer respiration, d entire cessation of mouth-breathing following directly on separation of the maxillary bones.

A Clinical Study of Sixty-two Cases of Intestinal Infection by the Bacillus Dysenteriæ (Shiga) in Infants.—nnæus Edford La Fetra and John Howland emphasize e following points: (1) The unexpectedly great prevaence of the dysentery organism in cases of diarrhœa in fants, at least during the summer months. Out of sixty-ir consecutive cases, sixty-two were positive. These re all ambulant patients, and were seen very early. All types of diarrhœal disease, as characterized by ir clinical symptoms, were found among these cases. me were severe, some were mild. The course of the ease was usually short. (3) As compared with cases of mmer diarrhœa" of other years those in this series re in general much milder. Possibly this was due to: The cool summer. (*b*) The increasing knowledge ong the tenement population of the care of infants and ir food. (4) The striking number of breast-fed infants, rteen in sixty-two cases, more than 20 per cent. of all. The serum treatment was not given in a sufficient mber of cases to warrant any conclusions. It may be t larger dosage is necessary; if so, the serum must be re concentrated than at present.

New York Medical Journal, March 12, 1904.

A Simple Method of Intestinal Anastomosis.—H. M. pperlen advocates the use of a gelatin cylinder, which ves as a firm support, is quickly introduced, and later omes absorbed. When it is in position he inserts a interrupted sutures through all the coats of the bowel insure coaptation. He then uses a fine intestinal silk, nty-four inches long, doubled, with a needle at each , having its knot where the ends of the silk are tied in center. He starts his first suture under the mesentery achment, inserting a needle with each hand at the same e through the two outside coats of the bowel, an eighth n inch from the cut margins. He then picks up a loop ut one-twelfth of an inch in length, according to the thod of Lambord, draws the parts together and ties m at each stitch, and continuing thus until he has mpletely encircled the bowel and closed the mesentery ning with the same suture, being careful to pass the dles under the small vessels in the peritoneal coat, so as to constrict the blood supply more than necessary. The vantages claimed for the method are: First, its simplicity; ond, it can be introduced, practically without handling parts, in about one-fourth to one-eighth the time uired for any other stitch, and third, when the bowels approximated by this method, they are held more ly than by any other stitch with which the author is quainted. Diagrams illustrate the different steps of procedure.

Senile Pneumonia; Value of Persistence in Treatment; Correct Method of Using Oxygen.—Solis-Cohen gives clinical history of a case of senile bronchopneumonia, dwells upon the necessity of persistent treatment. medies used in this special instance were nitroerin, digitalis, strychnine, atropine and alcohol, the ter in the form of champagne, which is better al whiskey for old people. Saline infusion under skin was given once. Hot flaxseed poultices were d for awhile, but later were replaced by a lamb's wool ket. The author makes a most emphatic plea for the ly and persistent use of oxygen where it is indicated. must be given over long periods, unless the patient is tressed by it. As a rule it promotes sleep. Nitrous ide may be combined with it as a sedative to cough and leep producer—about eight parts of oxygen to two of monoxide in cases in which opium (usually a dangerous g in pneumonia) would be needed. Low temperatures the disease the author regards as a bad omen, for they ow a want of reaction, while a high temperature inates a good vital reaction, perhaps the production of an titoxin. The coal-tar derivatives as antipyretics are itively dangerous, and the author believes that many sons die of pneumonia because their hearts have been akened by such remedies given in previous sicknesses or lf-administered for headaches.

American Medicine, March 12, 1904.

Pure Olive Oil and Its Use in the Treatment of Chronic ysentery and Allied Conditions.—Henry H. Rutherford scribes the process of obtaining the pure oil. Olives st short of full ripeness are selected for their soundness d healthfulness, and moderately rapid and complete pression made of them. The oily fluid thus obtained exposed to an even, dry air until all moisture is evapoted. From the treatment by olive oil of gallstone sease was suggested to the writer a trial of olive oil cases of chronic dysentery, sprue, and chronic enterolitis of tropical origin. The internal administration of olive oil largely increases the flow of watery bile The normal liquid bile in the intestine favors the absorption of fats; it stimulates intestinal peristalsis, it acts as an intestinal antiseptic. After the administration of olive oil in cases of chronic dysentery, there has been positive evidence of increased quantities of bile in the fæces. The number of bowel movements has been decreased, with marked improvement in their character. There has been a gradual cessation of signs of fermentation and putrefaction along the gastrointestinal tract and consequent subsidence of pain and tenderness; also general systemic improvement—gain in appetite, repair of digestive facilities, symptoms of improved nervous system, and rapid gain in weight and strength have been noted. There has been an apparent positive cure after an average time of two months and upward, with few recurrences up to date. The patient is given 30 c.c. of oil three times a day for the first three days, and the quantity is gradually increased. At first the oil is best taken with about equal quantities of hot milk, with which it practically forms an emulsion.

The Diagnosis of Metapneumonic Empyema in Infancy and Early Childhood.—John Lovett Morse concludes that: metapneumonic empyema usually develops during the last days of the pneumonia, or during the first days after the crisis, but in rare instances may develop in the early days of the pneumonia, or later during the convalescence. Persistence of the fever and other symptoms after the time of the expected crisis or their recurrence after the crisis should always suggest the possibility of an empyema. There is nothing characteristic about the symptoms of empyema, which are those common to all severe pulmonary affections. Rapid emaciation and progressive pallor are the most constant symptoms in neglected cases, while chills and sweating are unusual. Enlargement of the affected side as a whole is more common than flattening or bulging of the intercostal spaces. Flatness in Traube's space is less constant in left-sided effusions in infants and children than in adults. The most constant and characteristic sign of effusion is a marked sense of resistanc on the affected side. Displacement of the heart almost always occurs, and next to the sense of resistance is the most important sign. These two signs justify the diagnosis of effusion even if all the other physical signs are inconsistent. Dulness or flatness is almost always present, but may be replaced by tympany. The respiratory sound is almost invariably bronchial or bronchovesicular in character, and as a rule, diminished in intensity. Loud bronchial respiration is not uncommon, however, even with large effusions, and counts very little, if at all, against the presence of fluid. The vocal resonance is very variable both in character and in intensity, and is of little value in diagnosis. It is very difficult to determine the vocal fremitus satisfactorily. Its absence is an important diagnostic sign. Râles may be transmitted through large amounts of fluid. Their presence does not rule out an effusion.

The Etiology and Pathology of Arteriosclerosis.—H. B. Anderson gives as the sequence of events in the development of arteriosclerosis, a weakening of the media; dilation of the vessels and slowing of the blood stream; and a compensatory sclerosis of the intima. These stages do not occur consecutively in the different parts of the vascular system, but the weakening and compensation proceed hand in hand, especially in the early stages of the disease. The stress of the causative factors in different cases falls upon different parts, producing much diversity as to the frequency and degree with which particular vessels are affected. For this reason arteriosclerosis is of far more frequent occurrence, and shows far more advanced lesions than phlebosclerosis. Rokitansky enumerates the following parts of the arterial system in the order in which he thinks the relative frequency of their involvement occurs: The ascending arch, then the abdominal and thoracic parts of the aorta. Next follow the splenic, the femoral, the internal iliac, the coronaries, the cerebral, the uterine, the brachial, and the subclavian. Such, from the microscopical examination of the arteries in one hundred autopsies, found sclerosis most common in the arteries of the limbs, and the anterior tibial most often affected of all. Continuous high tension, increased by mechanical stress, explains the involvement of the aorta and its branches as the coronaries; strain and variations in pressure from muscular action account for the tendency to the disease in the upper extremities of manual laborers; the vessels of the lower extremities also support not only the hydrodynamic, but also the hydrostatic pressure of the blood. On account of variations in pressure associated with digestion, the splenic artery is likewise exposed to the disease. The frequency of the disease in the cerebral vessels is related to the functional requirements of a well-maintained blood supply, increased by occupations

attended by long-continued mental effort and worry. The kidney vessels are especially exposed to the causes of the disease from the fact that they are brought into contact with toxic substances in process of excretion. The forms in which arteriosclerosis manifests itself have been divided into the nodular, the diffuse, and the senile. Osler says that longevity is a vascular question. The nutrition and function of every organ is absolutely dependent upon a proper blood supply. Many conditions commonly recognized clinically as distinct maladies are really manifestations of this protean disease. The writer concludes by calling attention to the importance of general nutritional disturbances, the symptoms varying with the seat, extent, and distribution of the vascular lesions, so that an endless variety of clinical phenomena is possible, according as the blood supply to this or that part is chiefly affected.

The Lancet, March 5, 1904.

Four Cases of Tetanus Treated by Injections of Antitoxin into the Spinal Theca.—The cases are reported by C. S. Wallace and P. W. B. Sargent. The injections of the serum were made under strict asepsis between the third and fourth lumbar vertebræ. No untoward local effects were observed, either immediate or remote. The incubation periods of the cases here described were respectively six—six, nine, and eleven days. Three recovered and one died. Ten c.c. was the amount of the serum injected at one time. Chloral and bromide were also given.

A Case of Paroxysmal Labyrinthine Vertigo Associated with Special Ocular Symptoms and Alleviated by Seton.—T. W. Parry reports the case, his patient being a man of forty-three years. The two special points of interest in the case were: (1) the very unusual ocular symptoms occurring in a clearly defined case of Ménière's disease. These consisted of a sort of ocular vertigo. At first both pupils were equal, reacting normally to light and distance; he seemed to use the right eye more than the left, no myopia or hypertrophia could be made out, there was no paralysis of the eye muscles and the disks were normal. Later photophobia came on and seemed to stand in a causative relation to his attacks. (2) His most distressing symptoms were relieved by the seton at the nape of the neck after all drugs had seemed to lose their power. The use of the seton may be deserving, the author thinks, of greater frequency in vertigo of the nature described, and he is also inclined to believe that venesection, by unloading the intracranial sinuses would tend to relieve any hyperæmia there might be in the labyrinth, and possibly might procure excellent though temporary results.

The After-effects of Head Injuries.—This topic is considered by T. C. English in the third Hunterian lecture for the current year. His general conclusions are as follows: (1) Whilst some degree of mental impairment is comparatively common after injuries to the head, the changes are seldom sufficiently marked to be included under the heading of insanity. (2) Insanity may result from injury to any part of the head. (3) Traumatism leads to insanity in two ways: (1) direct insanity due to the actual injury to the brain or its membranes apart from hereditary or other predisposing causes; and (2) indirect insanity—that is to say, any form of insanity occurring as the result of lowered resistance of the brain due to injury in patients with a predisposition to insanity, hereditary or otherwise. (4) Every variety of mental change may be produced by traumatism, although some forms are commoner than others. (5) It is at present undetermined whether injury to the prefrontal region is more likely to be followed by mental disturbances than injury to other parts of the brain. (6) Only a small proportion of the cases of traumatic insanity are open to relief by operation, for a localizing indication in an accessible region must be present. (7) The results so far have been encouraging, and although the operation must necessarily be exploratory it is fully justified in suitable cases, especially in face of the otherwise hopeless condition of these patients.

Motor Symptoms in Mania and Melancholia.—W. H. B. Stoddart notes the occurrence in melancholia of paralysis and rigidity of the muscles of the spinal column and of the large proximal joints, the movements of the smaller and distal joints being comparatively unimpaired. The symptoms referred to are not always easily appreciable, as in mild cases they are scarcely noticeable. The movements of mania, on the other hand, take place during motor excitement, mostly at the large proximal joints. The trunk sways as the patient walks, and during running there is exaggerated movement at the hips. In the waving of arms, so frequent in mania, the greatest movement takes place at the shoulders and there is little at the wrist and fingers. The author concludes (1) that in mania an irritating product is formed within the cortical neurons; (2) that in melancholia a paralyzing product is then formed; (3) that in agitated melancholia there is a combination of deleterious substances, viz., a paralyzing product within the cortical neurons and also an irritating body in the plasma which bathes the nerve cell, and (4) that in a few cases of mania there is in addition to the irritating body within the nerve cell an irritating body in the plasma which bathes the nerve cell. Most of the delusions of the melancholiac arise from his feeling of inactivity, while the delusions of exaltation of the maniac arise from the feeling of activity due to the stimulation of his cortical centers. Hence arises the general idea of power, grandeur, etc., but the development of this kind of delusions is often disturbed by the occurrence of hallucinations, so that the feeling of activity is thrown into the background by the perversion of the senses.

British Medical Journal, March 5, 1904.

Treatment of Ankylostomiasis.—C. W. Branch states that his own routine is to give 30 gr. of thymol in powder at 4, 6, 8, and 10 A.M. on an empty stomach, followed by 1 oz. of castor oil at 6 P.M. This dose of 120 gr. of thymol is given regardless of age. The writer calls attention to Stockman's report on a case of ankylostomiasis which came under his care. Branch states that it is by no means the experience of those who deal largely with ankylostomes that they "are readily killed by large doses of thymol."

The Treatment of Hæmoglobinuric Fever.—H. Hearsey has treated eighteen consecutive cases of hæmoglobinuric fever without a single death. Sodium bicarbonate and liquor hydrargyri perchloridi are the drugs employed, in doses of 10 gr of the former and thirty minims of the latter. The combined action of these two drugs is antacid, diuretic, and disinfectant. Vomiting is allayed if not checked. The mixture is given every two hours for the first twenty-four hours, and afterward every three hours till the urine is free of hæmoglobin. Liquid nourishment is given, consisting of milk and barley water. Essence of chicken and meat juice are of value. As a stimulant brandy is given to the exclusion of champagne. All acid drinks are prohibited. Ferruginous tonics are given during convalescence.

On the Use of Oxygen Gas in Distending the Bladder for Cystoscopy.—A. Galbraith Faulds explains that in order to use the cystoscope one must distend the bladder in order to separate its walls. His method is as follows. He first drains the bladder through a soft worm catheter. A small rubber gas-bag is used for the oxygen, and is supplied with a vulcanite cock which fits into the mouth of the catheter. The oxygen is slowly and carefully pressed from the gas-bag, the catheter is withdrawn, and the cystoscope introduced. The use of oxygen must be practised with great caution. The patient must be warm and comfortable. The gas must be pure and be caused to enter the bladder slowly and with great care. If cystitis exists, it will be necessary to use a local anæsthetic. The gas can be left in the bladder.

Recurrent Fever Associated with Spirilla in the Blood in a Patient from Gibraltar.—Patrick Manson reports this case. The patient, a woman of thirty years, came under his care in December. Since October 20 the patient had from time to time suffered from fever ushered in by rigor and terminated by profuse sweating. Quinine had been given to the patient, on the supposition that she was suffering from malaria. The writer had blood films examined. These were prepared during the height of the attack. Four films out of six showed spirilla but no malarial parasites. The blood was examined for Malta fever and for pyogenic organisms with negative results. The writer believes that this was a case of spirillum infection, but whether the spirillum was that of ordinary relapsing fever, he is not prepared to say, although he is inclined to think it was different. The spirillum is not easily found. The writer urges careful microscopical examination of the blood in all cases in which the Widal test is negative or doubtful.

Observations on the Inception of the Rhythm of the Heart by the Ventricle as the Cause of Continuous Irregularity of the Heart.—James Mackenzie thinks that it may be considered demonstrated that the ventricle can take on the inception of the rhythm, and that when it does so the heart beats irregularly. It may further be presumed that whenever there is a continuous irregularity as distinct from occasional or rhythmic irregularity, the ventricle is giving the rhythm. Exceptions to this are rare. The writer believes that in paroxysmal tachycardia the ventricle also takes on the inception of the rhythm. The cause of the continuous irregularity is to be sought for in the exalted irritability of the heart muscle and not in the stimulation of the heart through the nervous system. The writer believes that the dilatation and ineffective action of the heart is secondary to the irregularity. Certain symptoms, such as uneasiness in the chest, weakness, shortness of breath, cyanosis and so on, which follow the beginning of an attack of continuous irregularity, are

hose we meet with in advanced cases, and for that reason he writer suggests that it is the irregularity that is the ause of the inefficient heart action, and not the dilatation that causes the irregularity. Treatment should be irected to lessen the irritability of the heart muscle and o protect the heart from being exposed to causes that xcite it to increased activity. The writer believes that rolonged rest in bed is the best remedy.

eutsche medizinische Wochenschrift, February 25, 1904.

Diphtheria Toxin and Antitoxin.—V. Dungern describes he animal experiments which lead him to believe that the iphtheria poison is made up of several components having different degrees of virulence and of affinity for the ntibodies. One of the less active of these is the toxon hich is still capable of producing lesions in the guinea-g, and a still weaker non-toxic component to which he ves the name of epitoxonoid. This assumption offers explanation of the fact that after the complete detoxication of diphtheria toxin, unsaturated bodies capable of ntralizing further quantities of antitoxin are still esent

The Volar Sound.—Hompeln describes a sound similar that heard over the carotid and subclavian arteries and curring in the palmar arch in certain cases. In common h the other auscultable vessels, the palmar arch is the t of a murmur in exophthalmic goiter and aortic inficiency. In many cases of arteriosclerosis the same nomenon is present in this region, and the author reds it as corroborative of the diagnosis of this disease. e author says that repeatedly his attention has been led by this sign to a beginning arteriosclerosis or conected kidney before arterial tension had risen to an appreble degree. Diminution in intensity of a previously l-marked volar sound points to progressive cardiac kness.

Choked Disk in Cranial Contusions.—Bachauer says that amount of disability produced after injuries to the ad is often very difficult to estimate, especially from the ndpoint of accident insurance. Usually the patient's ms of vertigo, persistent headache, etc., present no ysical evidence of their existence and malingering is en suspected. He describes two cases in which a mple concussion of the brain was accompanied by choked k and persistent headache. The first case apparently s complicated by an intradural hemorrhage and the oked disk began to appear on the fifth day and traces were l visible six years later. Though able to work, the tient was not altogether free from symptoms. The er case exhibited haziness of the optic disk five years er a cerebral concussion which had produced a pronced choked disk. Attacks of vertigo and headache o remained. The author calls attention to the fact that useful differential sign between choked disk and optic uritis is the fact that in the former visual acuity suffers t slightly, or not at all, while the reverse is the case in ic neuritis

Berliner klinische Wochenschrift, February 22, 1904.

The Hæmolytic Power of the Blood in Uræmia.—ator cites the observation of Neisser and Döring, who nd that blood serum from a uræmic patient, inactivated heating for one-half hour at a temperature of 56°, atly diminished the hæmolytic power of active serum m the same patient. That is, the addition of one c.c. the former to one-tenth c.c. of the latter prevented all molytic action. Two cases of the author's gave results inciding with this observation, but a third failed mpletely to show the expected phenomenon. The thor takes up the few other communications devoted this subject and discusses them at some length, but mes to the conclusion that the evidence is still too conicting to permit of generalization, and in view of the practical applicability of such a test urges that further work be one on a large number of cases.

Ultramicroscopical Observations on Glycogen, Albumins, and Bacteria.—Raehlmann publishes further observations with the apparatus of Siedentopf and Zsigmondy. This is a microscope equipped for the investigation of ultramicroscopic bodies by the addition of a means for intense lateral illumination. Under favorable conditions this instrument makes visible particles having a diameter of one to five-thousandths of a micron. In what appear to be chemically perfect solutions of glycogen—for example, minute particles of characteristic form are seen in active motion. With increasing dilution of the solution they become less crowded and more active, while finally a stage is reached in which they become scanty and are motionless. The author considers them as molecular complexes of definite structure, and believes that their motion is the result of the gravitational forces they exert upon each other. By the addition of diastase to such a solution the glycogen is changed to dextrin and the molecular change can be watched under the microscope, the particles becoming smaller and smaller and finally vanishing completely. By extending his researches to various animal fluids, the author has formulated a new theory for cataract formation depending on a change of the arrangement of the albumin particles composing the crystalline lens whereby its transparency is impaired. Very interesting observations on bacteria are also given, and the author believes that by this means the most accurate determinations of the comparative strengths of antiseptics can be made.

Münchener medizinische Wochenschrift, February 23, 1904.

The Precipitin Reaction Transmitted by Inheritance.—Merkel immunized three rabbits, one male and two females, to human serum. The females became pregnant during the course of the injections and one of them gave birth to five young. Two of these were immediately killed and their serum obtained. This was found to exhibit the same specific properties as that of the mother, though to a less degree of intensity. The author's intention to study the persistence of these characteristics in the others of the litter, as well as the effect of the mother's milk was frustrated by the early death of the newly born animals.

Poisoning with Male Fern.—Hackl reports the case of a robust man who, a short time after taking three drachms of extract of male fern, prescribed as anthelmintic, fell into collapse with cold extremities, perspiration, sunken features, dilated pupils reacting sluggishly to light, small slow pulse, labored shallow breathing, copious diarrhœa and repeated vomiting, convulsive movements of the extremities persisted for a day, and for two days the urine was rich in albumin and red blood cells. The treatment consisted in cardiac stimulants and counter-irritation. On the fourth day the patient had recovered except for general weakness.

Asthma.—Saenger describes a simple method he has found of great use in treating nine cases of asthma, of which the histories are given. His theory is that the deep inspirations the dyspnoic patient endeavors to make only serve to aggravate the existing over-distention of the lung and increase the distress. The patients should therefore be encouraged to inhale as gently and scantily as possible, and to make the expirations equally gentle but more prolonged. In order to effect this more easily, he has them count aloud, one count a second, up to four or five during the expiration, take a short inspiration, and so on, the diversion of the attention required also assisting to make the dyspnœa less urgent. Between the attacks similar exercises are systematically practised, extending the counting up to thirty or forty in the course of time. In this way the patients are inured to dyspnœa, as it were, and bear the attacks much better. The frequency of the attacks is also greatly diminished.

The Effect of Introducing Hydrochloric Acid Solutions in Achylia.—Heichelheim and Kramer describe the results obtained by testing the pepsin content of the gastric juice expressed after from 200–500 c.c. of decinormal hydrochloric acid solution had been poured into the stomach through a tube and allowed to remain for from one-half to three-quarters of an hour before being syphoned off again. A test-meal was then given and examined as usual. In some cases the test-meal was given immediately before introducing the hydrochloric acid solution. The authors point out the fact that the absence of free HCl without carcinoma is much less rare than is generally supposed. Out of sixty cases of achylia examined, only about one-third had positive signs of carcinoma. Achylia can also exist with but slight detriment to the health, as is shown by one case kept under observation for eleven years in which complete achylia has persisted all this time and yet the patient's nutrition has not suffered. For routine work in determining the pepsin content of the juice, the authors prefer the capillary tube method of Mett, although Volhard's method is somewhat more accurate and gives better results where close determinations are necessary. The dilution which Nirenstein and Schiff recommend in order to eliminate inhibiting substances, while theoretically correct, is not advisable, since the large multiplying factor (16) so introduced leads to inaccuracies in reading the digestion that has taken place in the capillary tubes. It was found that no formal rules could be established for the behavior of the pepsin content after the ingestion of hydrochloric acid solution in achylia, and the hope of elaborating a differential sign between simple achylia and that dependent upon carcinoma was not realized. The amount of pepsin was decreased in all forms of achylia, less in carcinoma than in the simple form. The fact that in carcinomatous achylia a relatively high pepsin content usually exists, which is still further increased by the hydrochloric acid treatment, may be found of some diagnostic use. A brownish discoloration of the returned HCl solution, due to blood, is evidence of carcinoma.

French and Italian Journals.

The Normal Salivary Microbic Flora.—A. Gilbert and A. Lippmann have reached the following conclusions: In the normal state, the canal of Sténon is invaded by an extremely abundant microbic flora; this microbic invasion is very marked even in the middle part of the canal, but grows progressively less as the parotid gland is approached. The tiny intraglandular canaliculi and the glandular parenchyma are sterile. The salivary flora is composed especially of anaërobic microorganisms. These far exceed the aërobic microbes in their constant presence, their number and their variety. These microorganisms are susceptible to certain variations according to the state of activity or repose of the parotid. During mastication, due no doubt to the mechanical action of the saliva, one can determine a notable diminution in the number of microorganisms. Prolonged fasting appears to have just the opposite effect.—*La Presse Médicale*, February 27, 1904.

Parasitic Hepatic Fever.—Pasquale Scarano says that a suppurative hepatic fever exists which has an intermittent type and that it commences in the bile ducts. This fever presents the same characteristics in the beginning as the intermittent hepatic fever, due to inflammatory processes of the liver. At first the diagnosis is uncertain between suppurative and true intermittent fever. But as the disease runs its course the differential diagnosis is much facilitated by the rapid increase of the grave symptoms and by the serious general condition of the patient. Another important diagnostic point is given by the character of the pain, which is not severe and much lighter than in hepatic suppurative inflammation. The fever under study has most of the characteristics of intermittent malarial fever which it closely resembles, but the symptoms follow no definite periodicity. As a general rule the disease is transmitted by contiguity of tissues rather than through the blood. The disease also resembles very closely typical septic fever. This form of fever should really be called bilioseptic, because this nomenclature indicates the starting point of the invasion of the germs, which is in the biliary tubes.—*Giornale Internazionale delle Scienze Mediche*, January 31, 1904.

The Dosage in Radiotherapy.—A. Béclère says that it is a general therapeutic law that all agents should be measured, and since Röntgen rays are a therapeutic agent they fall under this rule. By means of the r diochromometer of Benoiet the intensity of the *x*-ray can be measured. The instrument is made of a very thin silver disk, surrounded by twelve plates of aluminum, having thicknesses ranging from one to twelve millimeters. The principle of this mechanism depends on the variability of the proportion which exists between the absorptive power of the silver and that of the aluminum, which varies directly in proportion to the power of the rays. With weak rays the silver absorbs as much as the thinnest disk of aluminum, while the thickest aluminum disk does not absorb more light than the silver, thus allowing all the intermediate degrees to be noted. When the radiochromometer is exposed over a sensitive plate to a luminous tube the photograph gives twelve shades corresponding to the twelve aluminum plates, and in the center of them is the shadow of the silver disk. The aluminum disk shadow that corresponds in tint to the shadow of the silver disk indicates the intensity of the rays given off by the tube.—*La Presse Médicale*, February 3, 1904.

The Treatment of Cancer.—Th. Tuffier states that the *x*-ray has without doubt a selective action on certain cancers, and that this fact has aroused great hopes. Unfortunately the results that can be obtained in serious cases, such as epithelioma of the tongue and floor of the mouth, do not make a good showing. The *x*-ray has an undeniable action on the diseased tissues, which become softened and do not compress the nerves as much as before. This is shown by the frequent disappearance of pain, but so far this is the only change which has been proven in these cases. In the grave cases local applications do not seem to fulfil the requirements as well as some constitutional therapeutic measure might do. Serum therapy is what is needed in spite of the fact that all attempts to get one have so far been fruitless. Perhaps a definite chemical substance might be found which when injected would favorably modify the blood serum. Most of the anticancer serums from the very beginning can favorably modify the gravest neoplasms. The improvement is noted in the lessened extent of the diseased tissue which may shrink considerably as well as in the functional disturbances which may disappear after the first application. The later treatments are less effective and are finally powerless, allowing the diseased tissue to increase in extent more rapidly than ever before.—*La Presse Médicale*, February 3, 1904.

Influence of Traumatism on the Recurrence of Malaria.—Duret states that it may be questioned if fever which comes on after an operation in a malarial patient is due to infection or to malaria. The course of the temperature ordinarily suffices to clear up the diagnosis. In every case it is certain that the malarial symptoms may be renewed by traumatism. Verneuil has noted a recurrence of fever in malarial patients in cases in which it was impossible to admit infection, after simple contusions, for example.—*Journal des Sciences Médicales de Lille*, February 27, 1904.

A Pelvic-abdominal Syndrome in Women.—De Ran has often observed in women several symptoms (pain, neuralgia, hyperæsthesia, spasm, vasomotor trouble, congestion, ptosis, functional disorders, etc.) relating in various degrees to three systems which occupy the pelvic cavity: the genital apparatus, the digestive apparatus and the urinary apparatus. The pathological relation of these symptoms is accounted for by the richness of the vascular and nervous network of this region. This syndrome is noted especially in arthritics, neuroarthritics, hysterical patients and in neurasthenics. In certain cases it might be called pelvic-abdominal neuropathy.—*Bulletin Médical*, March 2, 1904.

The Prognostic Value of the Sphygmograph.—Giovanni Quadri attaches great value to the changes in the sphygmographic tracing in cases of heart failure and kidney disease. He cites a case of Reynaud's, of typhoid, in which there were no vascular changes until the twenty-third day of the illness, when the sphygmographic curve became markedly smaller, with marked changes in the circulation and purpuric patches on the neck and body, preceding death. To this he adds a case of his own of pernicious malaria with uræmia from acute Bright's disease, in which the sphygmograph enabled him to foresee the uræmic attack. The case was under the quinine treatment without any apparent effect on the malarial parasites. There was much albumin in the urine and hyaline and granular casts and renal cells. On the twenty-seventh and twenty-eighth days the patient had convulsions preceding death. Before the uræmic attacks there was a marked increase of arterial pressure, with an increase in the height of the sphygmographic curve.—*Gazetta Medica Lombarda*, February 15, 1904.

The Nature and Action of the Diphtheritic Toxin.—Giovanni Castronuovo has made some researches and experiments in reference to the theories of Ehrlich and Fraenkel. According to Ehrlich, a diphtheria culture in broth produces two substances, a toxin and a toxon. Both of these substances contain groups of atoms which can produce both toxic and antitoxic actions. Castronuovo concludes as follows: (1) The diphtheritic toxin contains substances whose composition is not at present known, and which in solutions of broth are not stable. (2) The toxin of Ehrlich cannot be absolutely demonstrated by experiment; the supposed specific manifestations of the toxon can also be explained by the action of the ordinary toxin. (3) The haptophore and toxophore groups of Ehrlich cannot be separated by heat, but remain quite hypothetical. (4) Attenuated diphtheritic toxin has a marked affinity for antitoxin, contrary to the theory of Ehrlich. (5) In a broth culture of diphtheria deprived of bacilli, after boiling, no immunizing substance can be demonstrated, thereby differing from the toxin of Fraenkel.—*La Riforma Medica*, February 17, 1904.

Lesion of the Larynx in a Case of Typhoid Fever.—P observed this interesting case. The patient was a young man of thirty-five years suffering from an attack of typhoid fever. His family as well as his personal history was bad. He was an alcoholic, and an inveterate smoker. About a month after he was first taken ill, and when the period of convalescence seemed near, he was seized with an affection of the larynx. The patient began to complain of difficulty in swallowing, and his voice became much hoarser than it had been before. The mouth and pharynx were carefully examined with almost negative results. By the next day the pain on swallowing was greater, the voice was weaker and there was aphonia from time to time. The respirations increased and dyspnœa developed. A laryngoscopical examination was not possible in the enfeebled condition of the patient. The symptoms increased in severity and tracheotomy was decided upon. The patient improved for a few hours after this operation, but soon began to lose ground and finally died. Autopsy showed necrosis of the cartilages of the larynx. The perilaryngeal cellular tissue was infiltrated by a small quantity of liquid of fetid odor. The writer thinks that whatever the microorganism that caused the lesion, the localization was produced because the patient was a heavy drinker and smoker, and because his larynx was not normal even on his entrance to the hospital, for at this time his voice was rough.—*Gazette Hebdomadaire des Sciences Médicales*, February 28, 1904.

Book Reviews.

s BLUES (Splanchnic Neurasthenia): Causes and Cure. y ALBERT ABRAMS, A.M., M.D. (Heidelberg); F.R.M.S. Consulting Physician, Denver National Hospital for Consumptives; the Mount Zion and the French Hospitals, San Francisco; President of the Emanual Sisterhood Polyclinic; Formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College, an Francisco. Illustrated. New York: E. B. Treat Company, 1904.

s a long time since we have read a medical book with interest and real enjoyment as we have this work. Abrams writes entertainingly on a novel subject, and ther his theory is fundamentally sound or not his book ggestive, and will at least do good in directing attento the neglected set of muscles which constitute the minal wall. He believes that the state of mental ression, popularly called "the blues," has a physical s in venous congestion within the abdomen, and as an ression of this belief he has adopted the term "splanchneurasthenia." This condition, he says, is characterl by attacks of depression, which come on spontaneously out apparent cause and depart as mysteriously as they . This form of neurasthenia is dependent essentially, lieves, on a stagnation of blood in the splanchnic or minal veins, which is either primary or secondary to us exhaustion. The treatment must therefore be ted against the local condition of abdominal plethora ll as against the neurasthenic state. The former is y of a physical nature, consisting in abdominal ge, abdominal and respiratory exercises, electricity, otherapy, and, when necessary, the wearing of an minal supporter. However, it is not merely in the ity of the theory and the seeming ease of cure that the n of the book lies, but rather in the author's evident ity and the easy, pleasant way in which he has oped his theme. The pleasure of the reader is ed a little by evidences of hurried proofreading, his is a defect which will, we hope, be remedied in e editions, for that there will be future editions can y be doubted.

ANGEBORENE KEHLKOPFDIAPHRAGMA. Von Dr. JOHAN N, Regimentartzt in Wien, mit 2 Tafeln and 2 ichnungen. Berlin: Oscar Coblentz, 1904.

author has collected from literature the records of en cases of this rare malformation, and gives a full ography thereof, adding two cases coming under its nal observation. The subject is given a careful and minating analysis.

SCRIPTION OF THE BRAINS AND SPINAL CORDS OF TWO OTHERS DEAD OF HEREDITARY ATAXIA, OF THE RIES IN THE FAMILY DESCRIBED BY DR. SANGER OWN. By LEWELLYS F. BARKER. Decennial Publations of the University of Chicago, 1903.

publication consists of a clinical report of two cases reditary ataxia by Dr. Sanger Brown of Chicago and tailed description of the gross and microscopic findings e brains and spinal cords, by Dr. Lewellys Barker. e are numerous illustrations of the cerebrum and bellum. The lesions in the spinal cord are beautifully trated in colored plates. Altogether it is an elaborate well executed essay.

ANUAL OF OPERATIVE SURGERY. By Sir FREDERICK REVES, Bart., K.C.V.O., C.B., LL.D., F.R.C.S. Sergeant rgery in Ordinary to His Majesty the King. New dition revised by the Author and JONATHAN HUTCHINON, Junior F.R.C.S. Vol II. 8vo, pp. Philadelphia d New York: Lea Brothers & Co., 1904.

second volume of this work shows, as did the first, y evidences of revision and elaboration. The necesfor this is apparent enough considering the advances le in the technique of operative procedure even since first edition appeared. The object lessons presented the illustrations are numerous and are leading features the work. The descriptions are models of their kind, leave nothing to be desired as to detail or lucidity. in these days when excellent surgical works are ndant, this one will commend itself to the practical geon as thoroughly covering the ground and meeting up-to-date conditions of the many vexed questions of cussion. This is particularly apparent in the section abdominal operations in general and particularly on pendectomy, in which the author has had an exceptionally large experience. The chapter on gall-bladder erations is also distinctive in this regard, as is also that ferring to the various operations on the kidneys. Nothing more than a mere allusion is made to the benefits of psulotomy for nephritis, as the author considers that its al value is still undecided. He is of the latter opinion garding Bottini's operation for enlarged prostate, as also ligature of the iliac vessels, castration, and vasectomy, and advocates direct and radical encapsulation when possible. The operation for the removal of breast cancer is described in much desirable detail, and the indications for the use of the knife are presented with such clearness that the merest novice cannot hesitate in appreciating their full force. The author believes in most radical extirpation of gland and clearing of axillary space, and while he admits that statistics have very much improved of late years, the present time limit of three years of non-recurrence of the disease is not an entirely reliable test of cure.

DR. JOSEPH LEIDY: A Portrait, etched by JAMES S. KING of Newark, N. J. Engraved surface 13½x16 inches. Limited edition of 150 copies printed on Imperial Japan Vellum paper and signed by the artist. Price, $15. Philadelphia: Published by William J. Campbell.

THIS is an admirable etching made by a capable artist from a portrait of the late Dr. Leidy. Leidy was a born naturalist, his interest in the natural sciences being manifested early in life and being actively maintained to the end. He was born in Philadelphia, was graduated from the medical department of the University of Pennsylvania at the age of twenty-one, and at thirty was elected professor of anatomy in his alma mater, continuing in the occupancy of his chair until his death. He was the first to point out, in 1847, the presence of trichinæ in pork.

The picture before us is a desirable one for its artistic merit alone; it is further worth having as the likeness of one of America's most distinguished scientists, and to graduates of the medical department of the University of Pennsylvania, and particularly Leidy's own pupils, it should possess especial attractiveness for the associations with which it is surrounded.

THE AMERICAN YEAR BOOK OF MEDICINE AND SURGERY, Being a Yearly Digest of Scientific Progress and Authoritative Opinion on All Branches of Medicine and Surgery, under the general editorial charge of GEORGE M. GOULD, M.D. I. Medicine; II. Surgery. Philadelphia: W. B. Saunders & Co., 1904.

THIS yearly digest fully maintains the reputation of its predecessors, and will be duly appreciated by the busy man who desires to keep abreast with the latest advances in medicine and surgery. The arrangement of subjects is everything that may be desired, and covers the field of progress in different lines very satisfactorily. The selection and treatment of topics is judicious and reflects great credit on the various experts in charge of the different departments of the work. In the present edition effort has been made to give a preliminary abstract or general introductory survey of the recent advances at the head of each division, which is a decided improvement on former plans. Although much partiality is shown in the liberal quotation of the editorial comments from the journal of which the editor of the work is connected, such a disposition may be pardonable on the score of inordinate zeal in a tempting direction.

THE PATHOGENIC MICROBES. By M. le Dr. P. JOUSSET, Physician to the Hospital St. Jacques, Paris. Authorized translation by HORACE P. HOLMES, M.D. Philadelphia: Boericke & Tafel, 1903.

MARK TWAIN long ago, in his translation back into English of the French version of his own classical Jumping Frog story, pointed out the pitfalls besetting the path of the literal translator.

Unfortunately the subtleties of the Gallic idiom lose their pungency when transferred *verbatim* into our own language, and while the original of this work is no doubt an instructive and gracefully expressed essay, in its present form it is calculated to arouse only amusement at its unconscious humor. *Traduttori, traditori!*

A TEXTBOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine and Clinical Medicine at the Medico-chirurgical College; Physician to the Medico-chirurgical Hospital; Formerly Physician to the Philadelphia and to the Protestant Episcopal Hospitals, Philadelphia; Fellow of the College of Physicians; Member of the Academy of Natural Sciences, Philadelphia. Sixth edition. Thoroughly Revised. Philadelphia, New York, London: W. B Saunders & Company, 1903.

DR. ANDERS' work is too well known to call for any special comments. In the present edition various subjects in the knowledge of which rapid advances have been made, such as yellow fever, bacillary dysentery, radiopraxis, etc., have undergone the necessary revision, and a number of new titles, among which are paratyphoid fevers, orthostatic albuminuria, trypanosomiasis, and transcortical aphasia, have been introduced. The author says that he has made free use of recent works and of the modern periodical literature in order to bring his book fully up to date in all essential points, and after a close examination of the chapters dealing with many of the subjects in which progress has been most rapid, we must admit that his claim is substantiated.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 3, 1904.

VIRGIL P. GIBNEY, M.D., VICE-PRESIDENT, IN THE CHAIR.

A Consideration of the Ultimate Results of the Bloodless Replacements of Congenitally Dislocated Hips.—Dr. JOHN RIDLON of Chicago read this paper, and said that in selecting his subject he had been actuated by divers motives, but chiefly with the hope that a straightforward presentation of the facts, in so far as he had been able to obtain them, might correct certain delusions and false impressions that had crept into the minds of medical men and others, mainly through uninformed writers of sensational articles in the newspapers. He said that for the past five years no subject had been so persistently misrepresented by the lay press and, he regretted to say, by the writers of the medical press, and nothing had been more misunderstood in that time than the results of these bloodless operations. He believed that enough hips had been operated upon and sufficient time had elapsed to gain an accurate knowledge of the facts which he wished to present. In bilateral congenital dislocations of the hip he believed this operation to be the only one to be used in every case, and he did not think that the bloodless replacement of these hips should be condemned if the anatomical replacements did not meet with more than 10 per cent. or 20 per cent. of successes. It was regrettable that people expected to get perfect results from this operation, but he thought the operators would be encouraged by the results thus far obtained in selected cases. The development of the operation was so well known to the profession that he did not think it necessary to go into its consideration. He divided his cases into four groups as follows:

FIRST GROUP.—From February 28, 1894, to July, 1897, these cases being observed by him in Chicago. In this group there were 12 patients, all girls, whose ages varied from 15 months to 11 years. Five dislocations were on the right and seven on the left side, and the shortening varied from one-half to two and a half inches. Only two of these could be traced.

SECOND GROUP.—From July, 1897, to the advent of Professor Lorenz. In this group there were 40 patients with 51 dislocated hips. At this point the speaker took up the consideration of what constituted a good result. Professor Lorenz, he said, considered shortening of the hamstring muscles as indicative of replacement, but Dr. Wilson of Philadelphia had demonstrated that this was not always true. The accidents which happened in the efforts at replacement were paralysis, fracture of the neck of the femur, fracture of the shaft of the femur, tear of the perineum, rupture of femoral artery, gangrene, etc. Of these 51 dislocated hips in this second group, 20 were on the right and 31 on the left side. Thirty-six were girls and 4 were boys. The ages varied from 18 months to 13 years, and the shortening varied from one-half to four and a half inches. Of the 51 hips, 24 were operated upon, and among these 5 were failures and 5 relapsed. All were cases of dorsal dislocation, except one, which was upward and forward. He then detailed some cases which presented points of interest.

THIRD GROUP.—Those that were examined and operated on by Professor Lorenz. Among this group there were 22 patients with 26 dislocated hips. Three were boys and 19 were girls. The ages varied from 2 to 12 years, and the shortening was from three-quarters to two inches. The results of operations on these 26 hips were, 12 anterior transpositions, 4 supracondyloid, 7 failures, 1 apparent, and 2 true replacement. In one there was a torn perineum, in another paralysis, one fracture of the neck, and one fracture of the shaft of the femur. He said that allowances should be made for Professor Lorenz' failures, because, after the operations, these little patients were no o nger under his care.

FOURTH GROUP.—This group comprised those that had been cared for by him since October 12, 1892. There were 42 patients, of whom 24 were girls and 18 boys. In 24 the dislocation was on the right side. The ages varied from 17 months to 13 years. The shortening was from one-half to three and a half inches. Of the 52 dislocated hips there were the following results: 7 anterior transpositions, 4 supracondyloid, 5 failures, 4 apparent replacements, 6 perfect replacements, 2 rejected, 4 refused operation, 6 still waiting for operation, 14 apparently in place at time of operation, but still in plaster splints. Fracture of the neck of the femur occurred in two cases.

Much interest was taken in the report of Case No. 33, which was given as follows: "On December 30, 1900, the right hip relapsed during the second month, while in the plaster splint, and the treatment of this hip was abandoned until a good result should be had on the left side. The plaster splint was removed from the left hip at the end of seven months, and the replacement was almost perfect. During the following three months the femoral head was forward, but not enough to be felt in the groin. Dr. Fenger was of the opinion that there was an anterior transposition, and as such I have reported it. The child walked on the limb for eighteen months without any striking result, and when Professor Lorenz operated on the right hip on October 13, 1902, he examined the left hip and said: 'That hip is good enough for anyone.' He did not say whether he considered it a perfect replacement or an anterior transposition. When Lorenz removed the splint from the hip he had operated on, the limb was found to be much shorter than the one I had operated on, but the head appeared to be in place. After three weeks of daily massage and manipulation, an anæsthetic was administered and the leg again stretched and manipulated and again placed in a plaster splint." Dr. Ridlon believed that this patient could now walk, but that a decade would elapse before it would be known whether or not there was a perfect result.

In speaking of the attitude of medical men toward bloodless surgery, he divided their interest into four phases: First, indifference; second, interest; third, delirium; fourth, the morning-after when things look different.

Notes had been taken of 129 patients with 158 dislocated hips. Of these 158, 93 were operated on and only 10 could be called perfect anatomical replacements. How many of 14 that are apparently in place, but which have not been *x*-rayed, that will prove to be permanent six months later was a matter of opinion. Some would likely show improvement. None of the dislocations originally dorsal had been demonstrated to have relapsed where the adductor muscles had been freely torn. Of the 93 there were 61 anterior replacements, 10 perfect replacements, 11 failures to replace, and 5 relapses. Of the 5 relapses, Dr. Lorenz operated on 2 and Dr. Ridlon on 3. When anterior transposition occurred, he believed it was due to freely tearing the tissues in front of the joint. When the supracondyloid occurred, he believed it was due to the saucer-shaped acetabulum. When the adductor muscles were not freely torn and the tissues were not overstretched relapses into dorsal positions might occur. It was his experience that if the femoral head was not buried in the acetabulum it was doubtful if one would get a permanent replacement; one was pretty sure to get an anterior transposition. Anterior transpositions frequently followed too violent operative measures. Retraction of the posterior muscles of the hip during the period of retention would cause an outward rotation of the limb which often would be found impossible to correct.

From his study of this bloodless operation it was his belief that in 100 cases 10 per cent. would become permanently cured, 60 per cent. would be only partially successful, and 30 per cent. would be failures. He reported a great many interesting cases showing skiagraphs and commented freely upon all.

Dr. WILSON of Philadelphia said that before the period

of delirium referred to by Dr. Ridlon, he dreaded those cases of congenital dislocations of the hip because nothing but disaster resulted, such as death, suppuration, ankylosis, etc., and he was not encouraged to pursue the subject, but all this was before the advent of Lorenz. Since his visit he saw the advantage of the operation and his own errors had been pointed out to him. In the Philadelphia clinic 20 cases were selected and presented to Lorenz for operation, and he selected a sufficient number to demonstrate his method. Among the 9 cases he operated upon he had the following results: In 3 there was a perfect anatomical replacement with good functional results; in 3 there were fairly good functional results; in 1 was not reduced, and in 2 it slipped after reduction. He was surprised at the expressed opinions regarding the value of the radiograph in these cases of congenitally dislocated hips, for he believed they were of great value when considered in connection with the clinical phenomena. He recalled the case of a boy, 4 years old, whom Lorenz had failed to cure. The operating was an absolute failure, that the Professor had exhausted his immense strength in the vain effort to start the muscles and set the hip. He said that Lorenz had been of great assistance in promoting bloodless surgery. but he personally knew of but 3 perfect results.

Dr. BRADFORD of Boston said that congenitally dislocations of the hip that had been observed in Boston had been carefully considered, and 130 cases had been reported and submitted to the public, and soon he hoped to have a statement prepared to present to the profession which would be entirely free from bias. This question he believed should be looked at without any so-called delirium. From a surgical standpoint there were certain facts that were not thoroughly understood. Now that we understood more regarding the pathological anatomy, an effort should be made to cure these patients, since the possibility of obtaining perfect results had been demonstrated. He believed that perfect anatomical cures should be strived for and could be obtained in a certain percentage of the cases. Taking the statistics as presented in Boston during the past twenty years, he said it would be found that the number of anatomical cures were steadily increasing, and by cure he did not mean functional cure or transposition, but a replacement of the head of the femur in the acetabulum with perfect restoration of the gait. In the future he believed this would be the result the surgeons should hope to obtain. He asked why relapses occurred, and thought that, in the majority of the cases, certain obstructions were present in the soft parts which might be overcome either by manipulation or by the knife, a question to be decided by the surgeon. At present it seemed to him that the manipulative method was the better one. In Boston mechanical force had been tried, and he thought the bone could be better guided in this way. In certain of the older cases he did not think reduction was practical, but in a large percentage of the cases occurring in children cure was not only practical, but possible, and was to be expected. He believed the future would show fewer relapses. He did not think it was any more impossible to cure congenitally dislocated hips than to cure congenitally clubbed feet. Of the 130 cases reported from Boston there were practically 40 per cent. cured, a very good showing.

Dr. SHAFFER thanked Dr. Ridlon for his careful and comprehensive analysis of the histories presented and said that, while not agreeing with all his conclusions, he thought the paper presented many valuable facts, and the statistics presented formed a valuable and intelligent basis, the only one thus far for judging the operation and its results. He was not prepared to give a satisfactory analysis of the results obtained in all the patients that had come under his observation, and he wished only to mention those which had been, for a longer or shorter period, under observation in the State Hospital. These were only four in number, and all were operated on by Lorenz at the Cornell Clinic.

The lessons conveyed by these cases, their behavior under treatment, their progress after the gypsum splint was removed, and the results thus far obtained, were very interesting. Even at this date he said it was impossible to state definitely the ultimate results, and it might be months or years before this could be definitely determined. In all these patients the tendency to the condition known as "anterior transposition" was very evident. He believed the statement made by Dr. Ridlon that this was due to the muscular condition produced by the tearing, especially of the adductors, was correct. In the after-treatment of this condition he believed that one should study the "adaptive muscular conditions" (as he had termed it) more closely. He said that muscles shortened or lengthened when opportunities were given, as in an acquired talipes equinus, associated with hip disease, or even more markedly in infantile paralysis or in lateral curvatures. A muscle torn and extensively lacerated by the force necessary to reduce a congenitally dislocated hip might be many months before it could regain anything like normal contractility. It might even be years. Studying the results which had come under his observation, he said he would in the future give those lacerated muscles a much longer time to recuperate—say a year or eighteen months—before discarding mechanical protection. In other words, after the plaster splint had been removed, a steel splint should be applied, as in infantile paralysis, embracing the pelvis, with a pelvic band, and embracing the entire limb to and involving the foot with antero-posterior motion at the hip, knee, and ankle, with or without perineal pads. This would place the femur under the control of the surgeon as regarded in- or out-ward rotation, and the "weight-bearing" principle could be applied while the patient walked about and in the line sought for, *i.e.* in the line which would maintain the head of the femur in the acetabulum. He believed that if this treatment had been followed in the patients he had watched, as well as some of Dr. Ridlon's, the percentage of perfect "anatomical repositions" would have been greatly increased.

Dr. WHITMAN did not consider the statistics of particular value, because, if Dr. Lorenz' method was properly carried out in younger cases, there were better prospects of cure. He believed that 40 per cent. of these little patients with congenitally dislocated hips could be perfectly cured by this method. If the bloodless operation failed he believed the open method should be tried.

Dr. A. JACOBI asked the earliest age at which babies should be operated on when they had congenital dislocations of the hip.

Dr. V. P. GIBNEY said that the cases at the Hospital for the Ruptured and Crippled were not yet ready to be reported, but he believed that their statistics would compare favorably with those given by Dr. Ridlon.

Dr. RIDLON, answering Dr. Jacobi's question, said the youngest child operated on was seventeen months old. There could be no question but that the earlier the operation the easier would it be; but, on the other hand, the younger the patient the more difficulty would be encountered in retaining the head of the femur in the acetabulum. He said it should be remembered that these little ones had very delicate skins and, being placed so long in splints, wet themselves and the splints, requiring frequent changes, possibly once a week for eight months. The period of choice was from two to four years.

Report of St. Elizabeth's Hospital, Chicago.—A report of the work of this hospital for the last year has recently been issued, which shows that 2,240 patients were treated. No remuneration was received for treatment in 411 cases.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held February 16, 1904.

L. A. CONNER, M.D., IN THE CHAIR.

New Instrument for the Determination of Blood-pressure.—Dr. THEODORE C. JANEWAY showed this instrument (see p. 358).

Demonstration of a New Aspirator.—Dr. CONNELL presented an instrument that had been in use at the New York Hospital during the past fourteen months. A large bottle was rinsed out with about three drachms of alcohol and the excess poured off; the alcohol was ignited, and as the flame was about to go out a stopper was introduced into the neck. Through the stopper ran a tube, which was connected by means of a rubber tubing to the needle. The air contained within the bottle was displaced by the flaming alcohol, so producing a vacuum. He said that from 70 to 80 per cent. of the air could be so displaced. It had been used to aspirate pus, for suprapubic aspiration of the bladder, for the relief of œdema of the leg, etc.

Notes on the Cytodiagnosis of Some of the Pleural Fluids with Particular Reference to the Tuberculous Form.—Dr. HERBERT C. CARTER read this paper and said that cystodiagnosis was a subject that until very recently had been entirely ignored. The importance of any additional aid in the diagnosis of obscure cases could not be overestimated. If a patient had a pleural effusion a positive diagnosis offered the best chance for his proper care. In fifteen cases out of 152 of pleurisy with effusion it was demonstrated to be tuberculous. In 3 per cent. of these the disease manifested itself within two years from the day of effusion. It was noted that when the specific gravity of the fluid was 1012 or above, it was an exudate, but if below that figure it was a transudate, and therefore this at once differentiated between the inflammatory and non-inflammatory fluids, and was a means of great value. So many of these pleurisies with effusion he said began the same way, and by means of this method of differentiating one could tell at once whether it was a pneumonic or an acute tuberculous pleurisy from the start. He doubted whether a true attack of rheumatism could give rise to a true pleural effusion. He then referred briefly to the morphological methods employed, and said that the fluids should be examined promptly after aspiration. Notes had been taken of the turbidity, reaction, the fibrin, albumin, and nucleoalbumin content, etc. The fluid was then centrifuged and examinations of cells made. The cases were divided into four classes as follows:

I. Cases of Pleural Effusion Proven to Be of Tuberculous Origin.—All cases gave a leucocytosis and the diagnosis was backed by autopsies on guinea-pigs, on the patient, or on both. The specific gravity was always over 1012. There was a large fibrin clot, a large amount of albumin, and a leucocytosis from 90 to 100 per cent. The relative number of cells contained in the fluid was of no importance, some showed endothelial cells in small numbers and others in large numbers. It was interesting to note that in these tuberculous cases there was a tendency to high temperatures. He believed that an almost certain diagnosis of tuberculous pleurisy could be made by this morphological examination of the fluid alone.

II. Cases of Pleural Effusion Probably of Tuberculous Origin.—Twenty cases were examined, and they gave practically the same characteristics as the fluid from those of proven tuberculous origin. The average specific gravity was 1019. The amount of fluid was from 6 to 159 ounces. The temperature ranged from 105 to normal. There were not enough cases to enable one to make any fair deductions.

III. Cases of Pleural Effusion Following Lobar Pneumonia.—Here there was a polymorphonuclear lymphocytosis with a large amount of fibrin, a large amount of albumin, and there was shown an exudative inflammatory character, with a specific gravity over 1012. This series of cases he said illustrated certain points in the differential diagnosis from tuberculous cases by a differential cell count. One might find polymorphonuclear leucocytosis before the third or fourth day in tuberculous pleurisy. The temperature curve when there developed a true course of pneumonia was that of the original disease and therefore high. There was a lower average temperature than that encountered in the tuberculous cases. The amount of fluid was from 5 to ounces, and, therefore, less than that of tuberculous origin.

IV. Transudates, from Cases of Chronic Nephritis, Endocarditis, Cardiac Dilatation, Acute Pericarditis, Etc.—The specific gravity in these cases was below 1012. The fibrin content was slight or none at all. The albumin simply appeared when nitric acid was added as a very faint or slight clowdy precipitate. There was a positive lymphocytosis present in all cases. The temperature curve was of no value. The differential diagnosis between transudates and tuberculous pleurisy he said could not rest on the differential cell count.

The Diagnostic Value of the Chemical Examination of Serous Effusions: Results at the New York Hospital.—Dr. JOSEPH C. ROPER said that the results examination at the New York Hospital were based twenty-six cases of fluid from the pleura, two from pericardium, twelve from peritoneum, two from ovarian cysts, and one from a mesenteric cyst. The points noted were color and general appearance, presence of coagulum, specific gravity, reaction, estimation of albumin and nucleoalbumin. The color varied from a light yellow in hydræmia to a dark red in fluid from tumor of the pleura. A fibrin coagulum seemed to be a constant feature in most of the fluids examined. The specific gravity varied from 1005 to 1030 and was roughly proportionate to the amount of albumin. The reaction with litmus paper was alkaline or neutral. For a rough estimate of nucleoalbumin an acetic acid solution was used, and, with inflammatory fluids, gave a fairly well-marked white cloud. Some reaction was obtained in all fluids and it was generally admitted that other substances would be precipitated by this agent, but there was no doubt but that it was more marked in the inflammatory fluids. Several cases of tuberculous pleurisy showed very rapid accumulation of fluid with the albumin percentage well maintained. He concluded by saying that considerable importance was attached to the routine examination of these fluids as an aid to diagnosis.

Results at the Hudson Street Hospital.—Dr. HERMAN S. PATTERSON said that the examination of fluids collecting in the serous cavities and in the subcutaneous tissues during the course of inflammatory processes, renal and cardiac disease, was started as a routine in the Hudson Street Hospital by Dr. L. A. Conner in 19[illegible] and the purpose of this series of investigations was to determine whether certain fluids possessed characteristic features which would serve as aids to diagnosis which other clinical methods failed to furnish.

In an analysis of fifty-four specimens of fluid it seemed to him possible to distinguish the following:

1. Fluids which were the result of acute inflammatory processes, so-called exudates. He concluded that inflammatory fluids, or exudates in general, had an alkaline or slightly alkaline reaction, had an average specific gravity of 1023, an average amount of albumin (in terms of Esbach) of 29.26 gm. per liter. On the addition of a drop of concentrated nitric acid they yield heavy massive clots of coagulated albumin, which sink quickly to the bottom of the tube and often adhere to the sides; they give fairly strong nucleoalbumin reactions.

2. Fluids, the collection of which was part of an acute nephritis. He concluded that nephritic transudates were of comparatively low specific gravity, had a comparatively small amount of albumin which precipitated

with concentrated nitric acid as a cloud of variable density and in general without clots or flakes. The nucleoalbumin reaction was present in a little over half the cases but to a less marked degree than in exudates.

3. Fluids resulting from cardiac insufficiency, whether primary or secondary to chronic nephritis. He concluded that in fluids which collected as the result of cardiac insufficiency there was a higher specific gravity than that of nephritic transudates and lower than that of exudates. The amount of albumin was more than that of nephritic transudates and was considerably less than that of exudates. The nucleoalbumin reaction was faint but more constant than in nephritic transudates. In conclusion he then cited a case to illustrate the practical value of this method of clinical investigation.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held November 20, 1903.

T. HALSTED MYERS, CHAIRMAN.

Dislocation of the Humerus Complicating Obstetrical Paralysis.—Dr. W. WHITMAN presented two cases illustrating the treatment of dislocation of the humerus complicating obstetrical paralysis. The method which he had employed was similar to that of the Lorenz reduction of the hip-joint. This was preliminary forcible manipulation to rtretch the contracted parts and reduction by hyperextension of the elevated arm which was then slowly carried downward to the side of the body and fixed by means of a plaster bandage. This was retained for several weeks or months, and on its removal manipulation and muscle training were, if possible, begun. In some instances it might not be possible to reduce the displacement at the first attempt. Cases of this character were sometimes classed as true congenital displacement or misplacement of the humerus, but they were, in most instances, secondary subluxations, induced by the habitual attitude of abduction and pronation characteristic of obstetrical paralysis. In certain cases, repair of the injury to the nerve trunks had taken place, and yet the function was disabled, because of the subluxation of the head of the humerus backward, which made supination of the forearm impossible. In such instances, the correction of deformity might accomplish a practical cure. In the majority of cases of this character, the paralysis was irremediable, but even in this class the reduction of the displacement improved the attitude and function of the arm.

The first case was that of a girl eight years of age, operated upon three months before. The reduction was successful, the attitude was normal, there was a fair range of motion in the joint, and apparently no paralysis of the muscles. In this case functional cure was probable.

The second case was that of a boy eleven years of age. The extent of the original injury to the nerves was indicated by the atrophy and loss of growth of the extremity. In this case reduction was difficult, requiring several sittings. Now, about one year after the operation, the head of the humerus appeared to be firmly fixed in the proper position. Although there was but little power of voluntary motion in the joint, the appearance and the function of the limb had been considerably improved by the reduction of the displacement.

Coxa Vara.—Dr. WHITMAN presented also a case illustrating the operative treatment of coxa vara. The patient was a girl, ten years of age, who had limped for two years, and had recently complained of much pain and discomfort. The treatment consisted in the removal of a sufficient wedge of bone from the base of the trochanter, to permit the restoration of the normal angle of the femoral neck. A thin layer of bone at the extremity of the wedge, formed a hinge, the two opposing surfaces being brought into contact by abducting the limb. In this maneuver the trochanter being fixed by contact with the upper border of the acetabulum, further abduction of the shaft closed the wedge-shaped opening. In this attitude the limb was fixed by means of a plaster bandage, until repair was complete. In the patient presented but slight trace of the former disability was evident, although the operation had been performed in September, the bandage having been removed about three weeks before this meeting.

Dr. V. P. GIBNEY said that he remembered seeing the operation. He thought at the time, that the stretching had not been done sufficiently well to get the arm far enough back to make the reposition, and reduction of the arm where it belonged, absolutely sure. The boy had been kept at the hospital for a long time. After the removal of the plaster it seemed to the speaker, he had had a little better range of motion than at present. He said all were familiar with the cases presented by the late Dr. Phelps. The open method had been adopted, but he could not quite see how a perfect result could be obtained until the parts could be held in better position, and for a longer time than by the present treatment. He thought Dr. Whitman was working in the right direction, and that by and by a perfect method of treatment for this deformity would be evolved.

Dr. H. L. TAYLOR said he judged that these affections were secondary to obstetrical palsy, and should be reduced by a system analogous to that employed in congenital hip dislocation. In this case the shoulder seemed to be in good position. There was subluxation of the end of the clavicle, which was not important, though quite prominent. There is limited use, but, as Dr. Whitman had said, it must be remembered that the arms were more or less palsied, and the getting of the head of the humerus into its socket and keeping it there was certainly an improvement in the child's condition, and an improvement over the cutting operation for getting the arm into position.

Dr. LAZINSKI said that he had been very much interested in the case several years ago when he had seen a number of these children. The condition was then ascribed to injury to the brachial plexus, fifth and sixth roots, paralysis terminating in luxation of the shoulder-joint. If the muscles did not undergo regeneration under treatment or spontaneously, there was permanent disability. The speaker was glad to see such good results obtained by manipulation without any other operative interference.

Dr. L. PIERCE CLARK said that he was very sorry that he could not know more definitely about the cause of this condition, particularly in regard to birth. He thought that these conditions figured as obstetrical palsy due to lesion by stretching the fifth and sixth cervical roots, although there often was injury to other roots. He had palpated the plexus in both cases. He could detect the site of lesion in both. He thought the range of paralysis in the boy was greater in the brachial plexus. He thought other roots could be found damaged far down in the plexus behind the clavicle. In obstetrical palsies the deltoid suffered most because it was most completely supplied by the fifth and sixth cervical roots; then the biceps and supinator brevis. Subluxation of the shoulder was secondary to the paralysis; the atrophy in the deltoid corresponding to the atrophy in the shoulder-joint. It is a painful condition, and while operation may enable the muscle to work at much better leverage, nerve section and suture must be done. Kennedy had done the most successful operations of this character recently. The speaker had, during the past year, looked up a series of cases on which Dr. Alfred Taylor had been doing nerve section and suture. The cases had been doing all that could be expected, but much time was required for reparative processes, and they were not ready for presentation, but would be in four or five months. In such operative work as that presented by Dr. Whitman, this operation would not influence the pronation of the hand, because that was dode by the supinator brevis. This attitude of marked internal rotation was present, not because the pro-

nators were weak, but because the external rotators had been paralyzed. As the condition gradually improved, the elbow came down to the side and contractions took place. Last in the process was pronation of the hand. He had never seen cases of obstetrical paralysis in which this lesion had been marked, in which there had been entire recovery of supination of the hand under any form of treatment. He said that massage and passive movements were disregarded by neurologists, as the patients never carried out the movements under their own volition. After operation, a series of educational principles had to be carried out, and afterward cerebral training was given. Representations of movements must take their position in the brain. The brain, and not the muscles, must be educated. The speaker thought Kennedy's brachial plexus operations more successful than others, because he applied the cerebral education principle.

The Chairman, Dr. MYERS, wished to know in how severe cases of these paralyses, Dr. Whitman applied reduction. Was it not possible, in some cases, to produce immobilization in this way at the shoulder-joint, and so secure more motion of the arm through the less paralyzed muscles acting on the scapula?

Dr. WHITMAN said he had studied the hospital reports carefully in thirty or more cases of obstetrical palsy, and had seen the patients come in, all having the well-known attitude belonging to this condition. There was at first no subluxation present at all; it was the effect of the continued pronation and abduction. For that reason Dr. Whitman thought passive motions of great importance in order to prevent such conditions as he had shown. Whether there was paralysis or not, he thought it better to have the head of the bone in the normal position. Then there was power to supinate the arm. In the case of the little girl, Dr. Whitman thought there would be recovery of function, because the injury to the brachial plexus had been slight, but in the other case there would never be recovery, as the injury had been great, as shown by the atrophy of the muscles. There was complete ankylosis of the shoulder-joint. It was better with complete ankylosis to have the head of the bone in its proper place, which was all he had attempted to show. In former times this bad attitude had been allowed to persist, now it was remedied. It was better to do this forcible operation in one, two, or three sittings, thoroughly stretching the parts, than to make a section posteriorly without stretching. Whether or not they could be successfully replaced, and whether they would stay in place, he did not know. He did not present them as favorable cases. Thus far, the bone had remained in position, and function was very decidedly improved.

Dr. Gibney asked Dr. Whitman whether he did not think it would be better to do an excision of the head of the bone in the boy's case, in view of the importance of having it in its proper place, thus giving the patient a more flexible joint.

Dr. Whitman replied that it seemed to him that the atrophy of the scapula and shoulder muscles was very great. The arm was considerably shorter than the other side. He thought excision would be of little use if there were not sufficient muscle to move the arm about. It was a difficult case at the time of operation, and he was obliged to attempt to replace the bone in two sittings. Had been perfectly contented to have complete ankylosis because the attitude was much better. The boy now had partial supination; he had none before. The boy had had no treatment after the operation, whatever, except what the mother had been able to give him, in the way of massage, etc. He thought in the reduction of all deformity of long standing, the operator should not attempt to do what was required in less than two or three sittings.

Dr. Taylor said he understood the presenter of the case to say the legs had been made equal in length. He was quite sure that the affected limb was half an inch shorter than the other. It was in excellent position.

Subluxation of the Tibia.—Dr. V. P. GIBNEY reported the case of a boy ten years of age, with marked flexion deformity and subluxation of the head of the tibia, presenting a long cicatrix below the patella. He thought on first sight, a case of exsection of the joint in early life and the usual recurrence of deformity that takes place in those cases. He wished it, however, placed on record, a malarial synovitis of the knee, or rather, synovitis occurring during malarial attacks, and wanted to bring up the question as to whether it was osteitis or pure malarial synovitis. Dr. Whitman had operated on the boy, doing osteotomy above the condyles. The leg was now quite straight. Dr. Gibney showed a radiograph of the limb and wished to call attention to the curving of the lower end of the femur which takes place in tuberculous lesions of the bone, and have it compared with the sound limb. The history of the case, in brief was as follows: Boy eight years of age. Entered Bellevue November 22, 1900. Family history negative, save for malaria, which attacked all members of the family just before the boy's admission to the hospital. Plasmodia had been found in the blood. At the end of November, 1900, the boy began to have chills followed by fever and sweating. This occurred every other day. He would have twenty chills, accompanied by nausea, vomiting, and diarrhœa. Also severe frontal headache. No epistaxis. Looked well nourished but slightly anæmic. Heart normal, slightly irregular. Temperature 102.2–105. On December 1 there was tenderness in right knee and elbow. The joints were swollen and stiff. The tenderness was most marked at the inner aspect of the tibia. The inguinal glands were swollen. On January 8 the joint was very painful. Marked contraction of the leg. Massage and passive motion given daily. Stools fewer, and more normal in character. On January 20 the joint was opened, and the cartilage was found diseased. This was scraped away completely, the bones being found intact. The quadriceps extensor was cut out to get the patella out of the way. Suture by chromacized gut. Skin sutured with silk. A plaster-of-Paris splint was applied from the hip to the toes. The boy was admitted to Hospital for Ruptured and Crippled November 5, 1903, with the deformity described by Dr. Gibney.

Adult Knock-knee.—Dr. GIBNEY also described a case of adult knock-knee. The patient was a large Swedish woman, thirty-two years of age. The knock-knee was very marked. Very little history could be obtained. On the inner side of the knee what seemed to be a very large mass appeared, not distinctly outlined. It was suggested of osteosarcoma, but the diagnosis was not positive and an *x*-ray was taken. This showed a much elongated internal condyle, and cuneiform osteotomy was done and the limb was brought around in perfect position without difficulty.

Dr. WHITMAN said that he thought the bending of the lower extremity at the knee not uncommon in flexion deformity so often seen.

Dr. TAYLOR related the case of an Italian with obliquity of the pelvis. The man complained of backache, and on examination marked pelvic obliquity was found. Short legs were not uncommon, but the trouble with this man was that one leg was longer than the other, which was normal. The condition was due to an old osteitis of the tibia. One leg was one-half inch longer than the other.

Dr. NAPIER said that unfortunately the patient of whom he would speak was beyond presentation. The case was one he presented at the April meeting of the section. A boy of fourteen who had lateral curvature with some rotation, beginning Pott's paraplegia. After the above meeting, the boy was ordered to bed. At that time the paralysis had somewhat increased. On Tuesday, April 21, a plaster jacket was applied in suspension. The paralysis had then extended along the legs, and was almost complete. There was nearly complete loss of sensation, loss of bladder control and no movement of the bowels. Ten

ature normal. The boy was kept in bed. April 22, he morning, nearly complete paralysis, loss of all power the arms, very little sensation. Involuntary evacuas, temperature normal. During the afternoon the thing became difficult. At five o'clock, on the 22d, died of paralysis, apparently of respiration. Dr. ier reached the house a short time after the boy died. presumed this case was one of ascending myelitis. He dered whether the contents of the abscess might not e entered the spinal cord, causing the rapid paralysis.

mpairment of Growth due to Cerebral Lesion.—Dr. MER presented this case. Young woman, seventeen rs of age, paralyzed since birth. No instruments were l, but the birth was tedious. Injured arm three es shorter and forearm one and three-quarter inches in greatest girth than the other. Face and chest on red side much smaller than the other side. Possibly arked case of so-called birth palsy. If so, involvet came from fifth and sixth cervical, because the e arm was affected; the extensors more so than the rs. Electrical reactions normal. Sensation normal. speaker thought, because of extreme failure of growth the fact that reactions to electricity were normal. paralysis was of the cerebellar or spastic type, rather of the spinal type. Legs normal. He agreed with Clark that it was the education of the muscles that of benefit in these cases.

ecimen from a Case of Marie's Disease.—Dr. ELLIOTT nted a spinal column from a patient who had had disease described by Marie. The patient was first by Dr. Elliott in 1897; was then examined under sthesia for diagnosis. He was suffering from acute in the coxofemoral joint, with great hyperalgesia d not bear the weight of the bedclothes. The hipt was found to be ankylosed. He was a Russian, ty-six years old, admitted to Presbyterian Hospital pain in knee. Came to this country to avoid army ice. Had been examined fifteen years previously, and nd qualified, as to size, for a soldier. On admission to hospital support and extension were applied to the e, and the symptoms subsided. In one and a half rs he returned with pain in left coxofemoral joint, ch was ankylosed, gradually extending to the lower t of the spinal column, extending to dorsal and vical regions, involving right hip, and subsequently the ulders to a much less degree. He developed pulnary tuberculosis. The bacilli were found, and that ase progressed hand in hand with the other. He d from tuberculosis about two months ago. The cimen was almost typical of that first described by rie in the *Revue de Médecine*, 1897 He described two es almost simultaneously with Bernhardt, almost ntical in involvement of the larger joints and the hip, the small joints remaining intact. The curvature was dual, the symptoms of pain and hyperalgesia subsided, d the man then suffered only from his ankylosed sition.

Dr. TAYLOR said that he had seen many specimens of f spines of this general character, but in those he had n, the ossification was usually more marked on the terior ligament, and in the lateral bands rather than median and often on one side more than the other. ses of spinal stiffness due to ossification of ligaments or to teoarthritis were exceedingly common, but it was only ently that they had begun to be recognized. In rie's cases the large joints were involved, but there ght be osteoarthritis of the spine not involving the ge joints and there might be osteoarthritis of the large nts without involving the spine. Sometimes the spine d large joints were affected in succession. Sometimes ere was deformity, sometimes not. The result depended gely on the rapidity of the process. If ossification ook place rapidly, deformity was not so likely to occur; f slowly, there was equal round-back on both sides, or lateral spinal curvatures also.

Dr. ELLIOTT said in reply to Dr. Taylor's remarks, that in all cases he had seen described under this type the anterior ligaments had escaped, as in this case. There seemed to be two or three different types of stiff spines, and he thought the variety in which the anterior ligaments were involved, was the stiff spine of ordinary arthritis deformans, where not only the large but small joints were involved, and there was throwing out of deposit. Here there was no such tendency.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At a stated meeting, held February 24, Dr. James Tyson read a paper entitled "A Note on the Treatment of Puerperal Eclampsia," in which he explained that the utility of morphine in the treatment of some cases of puerperal eclampsia and its failure in others is due to the fact that under the one set of conditions the nephritis present is of the parenchymatous variety, and under the other set of conditions the nephritis is of the interstitial type. There is evidence to show that in the presence of the former the kidneys are capable of a considerable measure of elimination, while in the presence of the latter the eliminative power of the kidneys is greatly diminished. Dr. Tyson also pointed out the danger from hypodermoclysis or the like without adequate provision for the release of the increased amount of fluid—for example, by sweating or bleeding or catharsis—and he advised that this provision precede rather than follow the dilution of the blood and the attenuation of the contained toxic matters. Dr. Francis M. Perkins delivered the "Address of the Retiring President," in which he considered the aims and objects of the society, its obligations to the profession, and its relations to the State Medical Society, and to the American Medical Association. Dr. Alfred Gordon presented a communication entitled "A Note of Cerebrospinal Symptoms in Infectious Disease, Apropos of a Case of Typhoid Fever." He reported the case of a man in whom in the course of what appeared to be a mild attack of typhoid fever there developed right hemiplegia, aphasia, loss of control of the sphincters, and increased reflexes in the lower extremities with hyperæsthesia. The complication was only transitory in duration, and the patient ultimately made a complete recovery. The particularly noteworthy features were the development of grave cerebrospinal symptoms in the course of an apparently mild attack of typhoid fever, and the transitory character of the manifestations. The most plausible explanation is that they were due to the influence of the toxic process on the cerebral cortex.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

At a stated meeting, held February 25, Dr. W. M. L. Coplin presented a communication entitled "The Early Changes in Arteriosclerosis of the Heart and Vascular System," supplementing his remarks with an exhibition of sections showing changes in the blood-vessels in various tissues at different stages of the disorder. The lesions result either from changes in the constitution of the blood, or from alterations in vascular pressure, however superinduced, and it is probable that the nutrient vessels of the vessels themselves suffer earliest. Dr. C. Y. White read a paper entitled "The Early Changes in Arteriosclerosis of the Kidney." He pointed out the difficulty in separating the sclerotic change in the renal vessels from that in the kidneys themselves. He considered in detail the etiology, pathology, and symptomatology. Dr. W. T. Longcope read a paper on "The Early Changes in Arteriosclerosis of the Gastrointestinal Tract," including also a consideration of the alterations of a similar character occurring in the pancreas, the liver, and the spleen. Dr. W. G. Spiller read a paper entitled "The Early Changes in Arteriosclerosis of the Nervous System." He pointed out the frequency with which sclerosis of the cerebral vessels is associated with hemorrhage in

the brain, and contended that miliary aneurysms are not so common as they have in the past been considered to be. Dr. Farr exhibited two specimens of mitral stenosis. Dr. D. Riesman exhibited a large sarcoma of the mediastinum obtained from a man twenty-five years old who had presented symptoms only for three or four weeks, death taking place suddenly as a result of exertion attendant upon excitement. The principal symptom of which the patient complained was shortness of breath, particularly on exertion, and interfering with the recumbent posture. The face was cyanotic, the veins of the chest were enlarged, a tumor was evident above the right clavicle, and a large area of dulness was present over the sternum, and the adjacent portion of the right chest. In addition to a metastatic nodule in the lung, there was apparently an anæmic infarct in the spleen.

Pittsburg Academy of Medicine.

At a meeting of the Pittsburg Academy of Medicine, on March 1, 1904, the president, Dr. Ewing W. Day, in the chair, Dr. J. M. Douthett read a paper on the "Development of the Mastoid Operation." He reviewed the history of the mastoid operation from 1557, when Vesalius first discovered and described the communication between the mastoid cells, down to the present day. He described the typical mastoid operation as introduced by Schwartze in 1873, modified later by Küster; these in turn modified and improved by Bergmann, Korner, Jansen, Stacke, and Taufal. Dr. Mills of Philadelphia said the subject, in its intracranial complication, had interested him greatly. He recalled two cases in which Dr. Deaver operated. One, a mastoid abscess, with purulent extension, disease in other parts, Dr. Deaver decided to open the mastoid, then, unfortunately, concluded to abandon the operation, in spite of finding pus. At post mortem, the case showed, in addition to mastoid empyema on one side, a purulent leptomeningitis on the other side. The case had paretic symptoms on the left side, with general cerebral symptoms, and the propriety of operating on the side indicated by general symptoms was considered, but it was finally decided to operate only on the side with aural symptoms. Dr. Mills thinks that in every case of this kind it is necessary to follow symptomatic indications, even though it is necessary to open both mastoids. He cited another case seen with Dr. Agnew, which had a history of injury to the frontal lobe, with an umbrella rib. In operating, Dr. Agnew failed to reach by only one-quarter inch the purulent focus at the end of the traumatic track. Dr. Mills also stated that every otologist should, alone or with others, study the evidences of intracranial disease to direct him in his operative work. Dr. Gant reported a case operated on by Professor Kocher in Berlin, at which time the value of lumbar puncture in diagnosis and prognosis was suggested. He asked the opinion of fellows on its value. Dr. Moyer asked Dr. Douthett for his opinion as to diagnosis. Dr. Diller wished to emphasize the necessity of operating in cases of doubt as to lesion or location, and exploration of successive locations, if not found in the first. He recalled a case seen in coma with a history of otitis and few antecedent symptoms. Operation was advised, but refused, and the patient died. At post mortem the case showed a purulent meningitis.

Dr. Jackson referred to some recent observations with the sphygmo-anemometer on the production of shock by the use of the chisel and mallet in operations for intracranial otitic diseases. Dr. Mills thought the use of the chisel depended largely on the skill of the operator. In the case of a skilful operator, such as Keen, the shock is probably not great. He mentioned a case of Dr. Keen's in which the osteoplastic opening was 3 inches in diameter in the frontal region, opened in twenty minutes. The shock was slight and the patient doing well. Dr. Mills thought it inconvenient to use the trephine or dental engine in cerebellar cases, but preferred not to have chisel and mallet used in any case except by the most skilful operators. Dr. Day regarded operation in more or less diffuse purulent meningitis, not localized, of no use; as he had had ten cases in the last two years, of which none recovered. But when it is a case of abscess with a localized focus, he considers the results comparatively good. In one case which he saw with Dr. Lippincott, he refused to operate, because of a meningitis, at first. Two days later the operation was done, and a cavity containing three ounces of pus was found. The patient died.

Dr. Elterich asked for the opinion of the otologists present as to certain cases in which, after a few days of discharge from the ear, followed by forward displacement of the auricle from swelling back of the ear. In many of these cases Wilde's incision results in a cure in a few days. He referred to a double purulent otitis complicating scarlatina. Dr. Day thought many of these cases are periostitis from burrowing of pus between the fibrous and bony external auditory canal. He said it was a common fallacy to think there were no mastoid cells in infants. He had had one patient twelve months old in whom the abscess cavity in the mastoid was large enough to insert a man's thumb. He said that a number of New York operators had tried lumbar puncture and abandoned it as useless.

Dr. R. Milligan referred to a case in a child simulating furuncle of the canal. On incision through the skin and aseptic dressing, it was cured in a few days. Said that Politzer's experiments with lumbar puncture were negative with one exception, and that was a case of general meningitis. Dr. Johnston asked if burrowing of pus along the canal did not occur in adults. Dr. Douthett in closing said that the Schwartze operation was adapted to early operation before extensive necrosis had occurred. As to Dr. Elterich's case with carious bone, he thought it would have to be treated radically, even though it were a case of burrowing of pus along the canal.

Dr. Johnston asked what was the shortest "Incubation Period for Scarlatina." He reported a case occurring in a few hours after exposure, but thought some previous exposure had occurred. He thought that more care should be exercised by physicians against conveyance of contagion. Dr. Elterich said the incubation period might be anywhere from six hours to five days.

Dr. Johnston also reported a case of "Chickenpox in a Man," aged twenty-eight years, in which the exclusion of variola was difficult, as he was afflicted also with acne. The same patient had measles a year previous. Dr. Day reported having been called in consultation in a case of otitis with scarlatina. He had worn overalls and jacket, with bath and bichloride ablutions later; yet one of his own children had developed scarlatina fourteen hours later, with no other known source of infection than himself. Dr. S. C. Milligan reported a case of scarlatina occurring in a man thirty-five years of age—twelve hours after exposure. Dr. Simonton called attention to danger from the physician's shoes as conveyors of infection.

Orleans Parish Medical Society.

At the regular semimonthly meeting of this society, held February 27, 1904, Dr. Gordon King read a paper on "The Treatment of Hay Fever by Dunbar's Antitoxin," in which he reported very favorable results in a series of cases treated late in the autumnal hay-fever season of last year. Of six cases, five were of the autumnal type, and one of the hyperæsthetic rhinitis or irregular type. The latter case was the only one indifferently influenced by the antitoxin, the rest being either quickly relieved or markedly improved by a few applications. In one, in which asthma was associated with the hay-fever symptoms, complete relief was obtained after one application. While still somewhat skeptical of the true value of the antitoxin as a curative agent in all types of cases, the author is most

vorably impressed with the antitoxin in as far as his perience justifies an opinion and bespeaks great advance the near future in the elucidation of that very vexing estion, the etiology and successful treatment of hay ver.

Dr. Homer Dupuy read a paper on the same subject, marking that at least one of the causes of this disease d been isolated, and was now attacked by the potent rgies of an antitoxin. Dunbar's experiments marked stinct advance, and from further clinical verification, re promise of a specific treatment when pollen proved be the external exciting cause. We are now in pos-ion of a list of the toxic and non-toxic varieties of n. The pollen theory is not exclusive. Dunbar's overy does not disturb the triad of etiological factors, ely: (1) A neurotic predisposition; (2) A local an-ly in the upper air passages; (3) An external exciting e. Appropriate local and general treatment would have to be addressed to such conditions. It is proved t the toxins of pollen are not identical. Here was desideratum to get a special antagonist for each par-lar pollen toxin. Only then can we give the specific toxin serum for the vernal, summer, and autumnal eties of hay fever. He reported cases which, on the le, confirmed the theory of Dunbar.

r. Otto Joachim read a paper entitled "Personal Ob-ations in Dr. Dunbar's Laboratory." While there he t over the entire work done by Dunbar in his hay-fever stigations, and as far as possible repeated the experi-ts upon which Dunbar built up his conclusions. In ition to the typical reactions of rye toxin on the con-tivæ of the persons subject to hay fever, observations made of reactions of solidago or goldenrod toxin. In e persons on whom rye toxin acted, goldenrod toxin inert, while on others on whom goldenrod toxin pro-d reaction, rye toxin proved non-irritating. Some -fever subjects react to both toxins. These reactions ld be controlled with antitoxin made from either in, but more certainly and with less antitoxin if the responding antitoxin was used. Emphasis was laid on prophylactic use of the antitoxin. The excellent lts achieved by the previous speakers would probably be equalled in every future case, but the results so far ieved by the use of antitoxin in cases responding to the of one of the other toxins, were far ahead of any other thod in giving relief to hay-fever sufferers. One had right as yet to speak of a cure until an active immun-g agent was found. In this field, as well as in the ntific investigation of hay fever, Dr. Dunbar has done foremost work, which takes a high place in scientific dicine.

Dr. Gustav Keitz reported "A Rare Case of Poisoning Copper," caused by the wearing of an alleged "electrical t," consisting of a number of copper and zinc disks, hich had been in contact with his skin. The chief points interest in this case were: (1) The facial paralysis oc-ring on the same side of the limbs, explained on the atomical distribution (decussation) of nerve fibers; (2) e complete paralysis of left thumb; (3) That, while the ison operated constitutionally, there was such a marked ference in effect between the right and left sides. lthough the absorption occurred almost entirely on the ft side, it appears that the left side was affected out of oportion to the right side, inasmuch as the poison acted nstitutionally.

Cincinnati Academy of Medicine.

At a regular meeting of the Academy of Medicine, held February 29, Dr. J. Henry Schroeder presented a brief paper on the "Administration of Potassium Iodide," in which he called attention to the fact that one fluidrachm of the saturated solution may contain from 58 to 124 drops, according to the method employed for obtaining the drop, and that consequently the amount of potassium iodide in each drop may vary from 0.4 grain to 0.9 grain; the drop does not contain 1 grain of the salt as usually supposed. Dr. Schroeder also stated that potassium iodide cannot form an insoluble compound with starchy food in the stomach, as sometimes taught. Disturbances of digestion are, therefore, not due to such an insoluble compound. Following this, Dr. H. J. Whitacre read a paper on "Pathological-anatomical Considerations Relative to the Bile Passages," which was based upon personal observations in the operating room, and the autopsy room. The autopsy material had been collected at the Cincinnati Hospital, and comprised a great variety of lesions of the gall-pladder, bile-ducts, pancreas, and liver. This autopsy material was given clinical importance by careful inquiry into the history of the patient, as obtained from hospital records, and relatives. The subject was considered from the anatomic and from the pathologic point of view. Clay, and other models were used to show the development of the upper part of the intestinal tract of the lesser peritoneal cavity, of the lesser omentum, and to explain the posterior and internal position of the entrance of the bile ducts into the intestine. The pathology was considered under the headings of (1) Gall-bladder and bile ducts; (2) the lymphatic system of this region; (3) certain diseases of the pancreas. Pathological material was demonstrated, and the following conclusions were based upon this study: (1) The anatomy of the upper part of the abdomen cannot be correctly understood without reference to embryological development. (2) Gallstones alone may produce symptoms by their passage through the bile-ducts, by their impaction in these ducts, or they may predispose to infection by interfering with drainage. (3) Infection of the gall-bladder is by far the most important factor in the pathology of this region. (4) The infection may be so severe that gangrene of the gall-bladder results, or it may be so mild that the patient is unconscious of the lesion. (5) Repeated mild infections will result in extensive alterations in the gall-bladder which render it functionless. (6) The common and hepatic ducts show inflammatory changes in the old cases of gall-duct disease that amply justify the clinical conclusion that such ducts should always be drained for a long time. (7) The advanced and the neglected cases will yield the fatal and the incomplete results in gall-bladder surgery. (8) Cholecystitis and pericholecystitis may occur without the presence of stone. (9) An infection of the gall-bladder sufficiently severe to cause pericholecystitis and extensive adhesions may occur without an acute illness which will direct the attention of the patient to this region. (10) Such adhesions may cause symptoms of persistent chronic gastritis, gastralgia, or intractable intestinal fermentation, and make of the patient a chronic invalid. (11) Primary cancer of the bile passages is much more common than was formerly supposed, and in its earlier stages is an operable disease. (12) Gallstones are the most important etiological factor in cancer of the gall-bladder. (13) The lymphatic supply is much more abundant in the bile passages than in the gall-bladder. (14) Enlargement of the hepatic or the common-duct chain of lymphatic glands may cause marked obstruction of the common bile-duct. (15) Acute hemorrhagic pancreatitis is caused in a certain large percentage of cases by the obstruction of the duodenal opening, of the bile duct with regurgitation of bile into the pancreatic duct. (16) Chronic interlobular pancreatitis is a disease which is very frequently caused by, or associated with, gall-tract disease, and must be treated surgically.

A Hospital with One Patient.—According to the *Daily Mail* of London, the special hospital for the treatment of ringworm, which the Metropolitan Asylums Board built at a cost of £200,000, remained empty until a few days ago when the record was broken by the admission of a child from Mile End road.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 12, 1904:

	Cases.	Deaths.
Measles	1579	23
Diphtheria and croup	353	44
Scarlet fever	496	21
Smallpox	5	...
Varicella	112	...
Tuberculosis	455	198
Typhoid fever	22	9
Cerebrospinal meningitis	...	10

An Irregular Manifestation of Malaria in an Infant.—H. Merriman Steele reports the case of an infant aged nineteen months, who was brought to him for the treatment of general prostration, restlessness, dyspnœa, pain on handling, and tumultuous heart action. The temperature was 106°, but four days later it had fallen to 101°. Quinine was then given and the child was well in five days. The special object in reporting the case was to urge the necessity of a blood examination in vague attacks with remittent or intermittent fever. In this particular case, the finding of the plasmodium saved valuable time in determining treatment. The lack of a leucocytosis threw out any consideration of septic processes to account for the fever. As to the "therapeutic test" with quinine, opinions differ, some authorities favoring it, others believing that it is of little value compared with a blood examination. In the case reported five days passed before the temperature was permanently controlled by the quinine. As a test, then, the writer holds that the microscope and quinine are not to be compared, and he believes that when a microscopical examination of the blood is possible, an injustice is being done the patient if that means of diagnosis is ignored.—*Yale Medical Journal.*

Optic Neuritis of Unknown Origin.—In the great majority of cases H. T. Pershing finds double optic neuritis is caused by organic intracranial disease, most frequently by tumor. In almost all of the remaining cases the cause is a general infection or intoxication. The number of infectious and toxæmic states that may possibly cause optic neuritis without intracranial disease is large, but this symptom is rare in any of them except uræmia. If inflammation of the optic nerves does occur in uræmia or in any of the infections, it is generally accompanied by retinitis. A similar neuroretinitis with hemorrhages is occasionally seen in severe forms of anæmia. Some local diseases outside the cranium seem, very rarely, to cause optic neuritis in a way not as yet understood. Thus disease of the upper part of the spinal cord, tabes, suppuration of the middle ear, and even suppression of menstruation, have been included in the list of causes. The author reports a case with intense double optic neuritis, which is most characteristic of tumor, occurring without any other disease, local or general, being found to account for it. In the other cases reported the original diagnosis of tumor or abscess, based mainly on the presence of optic neuritis, was wrong, and they even reported in the hope that they may contribute to an accurate estimate of the significance of this very important symptom. In two of the cases the author thinks it quite probable that the aural suppuration had some causal relation to the optic neuritis, but such cases are too few to serve as the basis of any confident opinion as to the mode of origin. In the third case he had no definite opinion of the cause. Even the supposition of an unknown toxic agent was not free from objection, for any symptoms other than the optic neuritis which might be attributed to intoxication were limited to about two days, and could be otherwise accounted for.—*Journal of Nervous and Mental Diseases.*

Birth Rate in Germany.—According to the Berlin co respondent of the London *Standard* there has been a stea decrease in the number of births in Germany during the p few decades. From 1870 to 1880 the number of births w 40.7 for every thousand inhabitants; during the follow decade it fell to 38.2 per mille; and from 1890 to 1900 was not more than 37.4 per mille, or about as much during the fifties. This decrease, however, has hithe been compensated for by the decrease in mortality. Fr 1890 to 1900, for instance, the death rate decreased more than 2 per mille. In Berlin the decrease in the bi rate has been especially marked; the total number births in the capital being 1700 less in 1903 than years ago. The actual number of births in Berlin 49,000 in 1903, and 52,259 in 1901.—*British Med Journal.*

Health Report.—The following cases of smallp yellow fever, cholera, and plague have been repo to the Surgeon-General, U. S. Marine Hospital Ser during the week ended March 12, 1904:

ODIDE OF POTASSIUM A SPECIFIC IN LOBAR PNEUMONIA?

A PRELIMINARY REPORT.

By H. ALTSHUL, M.D.,
NEW YORK.
TENDING PHYSICIAN, DEPARTMENT OF DISEASES OF THE CHEST, BELLEVUE OUT-DOOR POOR, ETC.

RVATIONS on sixty-two cases of my own ex- g over a period of twelve years, without a directly attributable to the disease, and over times that number of cases treated by colleagues request, with results approximately similar, aused me to question if iodide of potassium is not ch of a specific in lobar pneumonia as are e in malaria, mercury and the iodides in syphilis, on in anæmia.

bar pneumonia, with a mortality of from 20 per cent., is probably the most fatal of the ious diseases, and in the list of all the fatal dis- to which man is subject, Wilson Fox gives it h position, while Walshe ranks it as third. With- last decade there has been no change for the r in the death rate from the disease, indeed authorities claim that the mortality is con- ably higher than it was twenty to thirty years

With these facts before us a mortality of less 1 per cent. in over two hundred and fifty cases, es ranging from sixteen months to seventy-six s, a number of them in persons living under the unfavorable conditions, suffering from chronic carditis, chronic nephritis, phthisis, etc., is this nough to raise the question whether, after all, ave not a specific for the disease?

e inference is a fair one that when a drug which pidly absorbed and diffused is well borne, with- he slightest untoward effect when given in doses arily causing pronounced and toxic symptoms, drug is doing some work, and that its physio- al effects are required by the system to counter- he effects of some abnormal condition or disease. note this in the tolerance of quinine in malaria, in anæmia, morphine in the presence of pain,

he possibility of the existence of an idiosyncrasy t always be remembered, but is it at all likely every one of this large number of patients uld have been tolerant of doses of from five hun- d to three thousand grains per day of a drug like ide of potassium, which, as a rule, in the majority of s will cause distress and untoward symptoms in s of sixty grains per day? In syphilis, it is true, e effects are not common; yet their occurrence y no means a rarity, even in this disease.

How can we otherwise explain the absence of toward symptoms, the remarkable tolerance of h doses of the drug, than by assuming that its ion is expended in antagonizing the disease and effects?

Before proceeding to a report of the effects of the g in the disease, it may be well to review its ysiological action.

Iodide of potassium is one of the most readily absorbable, and perhaps the most diffusible drug we have. After its ingestion iodine can be demonstrated in the saliva and urine (the iodine reaction has been obtained in the latter in three minutes; Purkinje in Eulenburg's "Real Encyklopädie," Vol. 10, page 467), in all the viscera, the glandular and muscular systems, the blood, the sweat, in pleural exudations, in the synovial and conjunctival fluids, in the contents of abscesses—in fact, in all the secretions and excretions—and it seems to diffuse rapidly and to permeate every portion of the human body. Its absorption from the rectum is almost as rapid as from the stomach; after the application to the skin of a lanolin ointment of the drug, traces can be found in the urine in thirty minutes, and in four hours a decided reaction is obtained. Absorption from the subcutaneous tissues takes place with exceeding rapidity, and persists even in the death agony (Rozsahegyi, *Jahresbericht über die Fortschritte der Pharmac.*, etc., 1878). The reaction is least marked in the fæces, and disappears most rapidly from the blood.

Potassium iodide is changed into sodium iodide in the stomach, and is absorbed in this form. In the tissues, probably in the blood, iodine is liberated, probably through the action of the protoplasm, the blood cells, etc. Professor Binz believes that in this manner—that is, the continued liberation of the iodine from the circulating alkaline iodide—the action of the drug on the cells, and its bactericidal effect on infecting microorganisms is to be explained.

Elimination of iodide of potassium doubtless takes place by the bronchopulmonary, faucial, and salivary glands, but chiefly by the kidneys. (Bartholow, Fifth edition, page 229.)

The effects of the drug are: (1) Antiseptic and antizymotic; (2) markedly increased activity of the lymphatic system, and hence increased production of leucocytes, and increased absorption of products of inflammation; (3) increase of the alkalinity, and lowering of the specific gravity of the blood; (4) very decided vasodilator action, and thus cardiac stimulation; (5) direct cardiac stimulation through its base, and through increasing circulation in the arteries supplying the heart; (6) diuretic; (7) diaphoretic; (8) antipyretic; (9) respiratory sedative.

In lobar pneumonia we find the following conditions and symptoms which require our attention: (1) The toxæmia; (2) the diminished respiratory surface in the lung; (3) the relative hypoleucocytosis with reduced alkalinity and increased viscosity of the blood; (4) the venous engorgement and laboring heart with a tendency to weakness from overdistention of the right cavities and depletion of the left, as well as from malnutrition due to insufficient and badly aërated blood supply, and from impaired nerve power (Douglas Powell, *British Medical Journal*, November 9, 1895); (5) the impaired action of the kidneys and glandular system; (6) the pyrexia; (7) the cough.

Let us see in how far these conditions are affected by the physiological action of the drug.

The Toxæmia.—As before stated, Binz (*Archiv für exper. Pathol. u. Pharm.*, 1880) believes that

there is a continued liberation of iodine from the circulating alkaline iodide. Although the truth of this opinion has not been proven, yet it is generally accepted by physiologists and other authorities. According to Miguels' tables of antiseptic values, as given in Sternberg's "Manual of Bacteriology," page 179, iodine in a solution of 1 : 4000 is "*very* strongly antiseptic," while carbolic acid in a 1 : 333 solution is stated to be only "strongly antiseptic." I mention this comparative value because the opinion seems to be quite a general one that the treatment by means of the creosote and guaiacol preparations, all of which enter the circulation as carbolic acid, is perhaps the best now carried out. Owing to its greater antiseptic value in very much weaker solutions, its more rapid and complete diffusion, its freedom from toxic and dangerous effects, the facility and rapidity with which saturation of the blood and tissues can be obtained, the iodide of potassium is for this purpose of very much greater value. F. Schwarz (*Deutsche medizinische Wochenschrift*, January, 1881), who has obtained very favorable results from the use of iodine and iodide of potassium in the early stages of pneumonia, regards the effect obtained as due entirely to a specific action on the microorganism. He regards iodine as a genuine specific if employed sufficiently early in the disease, within twenty-four to thirty-six hours after the initial chill. As to a possible specific action of iodide of potassium on the pneumococcus, the investigations of Dr. N. L. Deming, now in Fort Wayne, Ind., are of interest. While house physician at the City Hospital on Blackwell's Island he examined the oral secretions of some forty epileptic patients, and found the pneumococcus present in all but five patients, while after a course of iodides it was absent in all but five. From this we can infer that the iodine in the saliva rendered this secretion unsuitable to the life of the microorganism.

Willebrandt (*Virchow's Archiv*, 1865, XXXIII; 1869, XLVII) reports favorably on the germicidal action of iodine in typhus, typhoid fever, and malaria.

L. Stopp (quoted in Eulenburg's "Encyklopädie," Vol. X, page 474) claims similar results in the treatment of diphtheria.

Kitasato, page 185 of Sternberg's work, is quoted as stating that typhoid bacilli and cholera spirilla do not grow in culture solutions containing 8 per cent., and are destroyed by five hours' exposure in a 9.23 per cent. solution.

In Hare's "System of Practical Therapeutics," Vol. II, page 596, under the heading of "Antiseptic Treatment" of pneumonia we find "Benzoate of soda, iodine, salicylate of soda, iodide of ethyl, and carbolic acid are especially recommended as antiseptics. Of these the results obtained from iodine are the most striking."

Leucocytosis.—A number of observers, notably Ewing and Cabot in this country, Loewy, Richter, P. Jacob, and others abroad, have found the presence or absence of leucocytosis to be a marked factor in the course and outcome of the disease. They all seem to agree that a hypoleucocytosis almost invariably means a fatal termination, and that conversely, as a rule, the greater the hyperleucocytosis the more favorable the course of the disease.

Leowy and Richter (*Deutsche medizinische Wochenschrift*, 33, 1895, page 241) found that animals in whom they had previously produced a marked hyperleucocytosis through injections of protalbumoses, pilocarpine, etc., resisted to a marked degree artificial infections. They survived inocu- lations of three to four times the lethal dose microorganisms. It was particularly noted the infected animals showed but very tri febrile reactions, and that the manifestation disease were but very slight. They state " therapeutic effect in pneumococcus infections, only infection which we have as yet investi in this regard, was a strikingly brilliant one."

P. Jacob (*Zentralblatt für innere Medizin*, 17; 1897, 18) expresses himself as believing we can favorably influence the course of infec diseases through the production of an artificia perleucocytosis.

The greatly increased activity of the lymp system and the great glands, following the iodide of potassium, is well known and undisp While the effect of the iodides on the producti a hyperleucocytosis is perhaps not so great as of the protalbumoses, spermin, neucleins, carpine, etc., yet the disadvantages and da in the use of these agents more than counterb their greater effect in this direction.

Diminished alkalinity of the blood.—Loewy Richter (*Deutsche medizinische Wochenschrift*, page 529) quote Neumann as finding tha artificial reduction of the alkalinity of the produces a diminished resistance of the a toward infection by microorganisms. They quote v. Fodor as proving a marked incre the power of resistance to infection of anim whom the alkalinity of the blood had be creased through intravenous injections of m alkalies. They further state that, accordi him (v. Fodor), there is a certain definite pr tional relationship between the degree of alka of the blood and the susceptibility to infec They themselves, having noted a marked inc in the alkalinity of the blood in leukæmia, favorably progressing pneumonia, septicæmia, infer a definite connection between leucocy and the blood's alkalinity. They further found the intravenous injection of agents causing inc of the alkalinity of the blood, enabled rabbi survive a pneumococcus infection to which co animals succumbed in from twenty-four to f eight hours.

F. Kraus (*Berliner klinische Wochenschrift*, 1893, page 876) has observed a marked reducti the alkalinity of the blood in typhoid fever, erysip scarlet fever, pneumonia, etc., and that the no degree of alkalinity is not reached until co lescence is established.

Meyer (*Archiv für exp. Path. u. Pharm.*, Vol. page 304) suggests a marked reduction of the blo alkalinity as possibly causing a paralysis of the tral nervous system, and that the introduction alkalies might be productive of favorable resu He quotes Burckhardt's experiments, in which was found that the intravenous injection of a s solution into rabbits which had been tetanized to beginning paralysis seemed to cause a revivify effect on the lost irritability of the vasomotor c ters. As Geppert proved that progressively w the temperature rise in high fever there is a p portional diminution in the alkalinity of the blo Meyer suggests the use of alkaline drinks, inst of the customary mineral acids, on the appeara of the first signs of impending coma or heart fail in hyperpyrexia.

For the purpose of alkalinizing the blood we kn of no agent so effective as the potassium salts.

The vasodilator action of iodide of potassium is great importance in reducing the arterial tensi and thus diminishing the burden placed on t right heart by the over-distended venous syste

has been claimed by Romberg, Van Santvoord, others that in pneumonia the peripheral blood-sels are relaxed as a result of vasomotor paralysis, that the characteristic and usually found pulse not one of high tension as has been supposed tofore. *Post hoc, ergo propter hoc*, is a very erous and unscientific manner of reasoning, yet how can we explain, otherwise than by ac-ing a state of high tension, the marvellous effect proper dose of the nitrites in the threatening yxia of pneumonia, as so graphically described rof. Andrew H. Smith. He says "By the use ese agents the pulse is changed from being and creeping in character to the large soft tion of low arterial tension. With this change spirations will be found to be less frequent and abored, the mucous râles in the chest will di-h, and the entire function of respiration and lation will undergo marked improvement." patient, cyanotic and dusky from asphyxia, s his color, even to the extent of becoming ed. The effect of the nitrites as given by Brunton arm.; Therap.; and Mat. Med., "Third edition, 785), to whom we owe our knowledge of the n of these agents, and whose conclusions are rsally accepted, is that they reduce blood-ure by dilatation of the arterioles, this being o weakening or paralysis of the muscular walls e arterioles themselves, or of the vasomotor ia in or near them. This is shown by the ing of blood-pressure by amyl nitrite after the has been cut just below the medulla.

e effect of the nitrites in pneumonia would to disprove most absolutely the contention of Santvoord and Romberg, as in this case in-of the favorable effects quoted we would have r an exaggeration of the symptoms of asphyxia, advanced cases, when the vasomotor paralysis ed by them is complete, no effect at all.

e vasodilator action of the iodide is of further in counteracting the effect of the greater ity of the blood, which, by increasing the on resistance between the blood and the vas-walls, adds additional burdens to the heart.

e viscosity of the blood is also considerably ced by the lowered specific gravity; in conse-ce of the greater abstraction of the circulating , through the urine, its fluidity is increased.

indirect cardiac stimulant through its effect he peripheral vessels, the iodide of potassium is a direct stimulant through increasing the circu-n of the vessels of the heart itself, and thus roving its nutrition (Prof. Germain Sée, *decine Moderne*, July 2, 1893). The same au-in *Bulletin Médical*, August 15, 1889, refuting theory that potassium salts are direct cardiac ons quotes the Irishman as consuming daily -1300 grams of potatoes in which he gets 72–80 ms of potash. He considers iodide of potassium a cardiac tonic, and employs it in cases of dysp-a of cardiac origin with excellent results. (Re-ted in the *Lancet*, as read before the French demy of Medicine, October 26, 1889.) Huchard Maladies du Cœur," Paris, 1889) holds the same w.

The diuresis produced by the iodide, probably to the increased circulation and direct stimu-ion of the secreting cells, is of value not only in ieving the heart, but in the increased elimination the waste and the toxins.

The antipyretic effect is probably due to the vas-lar dilatation and to the diaphoresis, permitting aporation and thus cooling the surface and the ood. Trasbot (*Tribune Médicale*, October 19, 889), in addition to claiming a reduction of tem-perature of one degree or more after the ingestion of iodide, states that there is a decided slowing of the respiratory rhythm, and to this he attributes a part of the favorable influence of the drug on cardiac and bronchial affections.

The liquefaction and absorption of the products of inflammation tend to diminish the cough, so distressing in some cases, to facilitate expectoration, and to lessen pain.

From the foregoing we have seen that the symptoms and conditions found in lobar pneumonia are antagonized and controlled by the physiological and therapeutic effects of iodide of potash, and my experience, as well as that of my colleagues, in the large number of cases in which it was used, is confirmatory of this.

In my own cases, sixty-two in number, a detailed report of which is at this moment impossible, owing to my inability in the short space of time at my disposal to gather and arrange the histories, charts, etc., but which will appear in a later paper, in addition to the influence exerted by the drug over the symptoms and conditions before stated, certain changes in the course and character of the disease particularly impressed me.

1. In none of the cases was there the least semblance of a crisis, the invariable termination being by lysis. This applies to both temperature and general condition of the patient. This gradual change is remarkable, as usually about 80 per cent. of the cases terminate by crisis. The most probable explanation of this difference seems to me to be that the antiseptic and bactericidal action of the drug inhibit the growth of the pneumococcus, hence there is a diminution of the toxins produced. These toxins being in circulation in but small quantity, their effect is readily counteracted. The control of the symptoms alone through the action of the drug is hardly sufficient explanation for the change from crisis to lysis.

2. In spite of the generally favorable action of the drug, the duration of the disease is not shortened.

3. The temperature even in cases of apical pneumonia was never very high, rarely exceeding 103°, never above 104°, when treatment was commenced early in the disease.

4. Complications, endocarditis, pericarditis, œdema, embolism, etc., were never met with. In one case, to be reported later, seen in consultation with Dr. L. Neumann of this city, a young woman with advanced phthisis developed a peritonitis; in the course of this a pneumonia appeared, and within forty-eight hours a meningitis. The lungs cleared entirely, the symptoms of meningitis had disappeared, and the patient was fairly on the road to recovery from the acute illness, when an intestinal paralysis, which had previously given considerable trouble, again set in and the patient died in consequence.

5. If the treatment was commenced within the first thirty-six hours after the initial chill the disease was at no time of the violent type with marked cerebral symptoms. If these symptoms were already present when the treatment was instituted they rapidly disappeared, usually within twenty-four hours, and the patient, who previously was perhaps wildly delirious and intractable, became calm and rational. Headache was the exception, and when present was very slight and of short duration.

6. In all cases, the patient treated with the iodide seemed to feel very much more comfortable, and seemed less ill than usual.

We have thus seen that, in addition to the symptoms, the very important and perhaps vital factors in the course and outcome of the disease, the toxæ-

mia, the leucocytosis, the blood's alkalinity and the condition of the heart, are most favorably influenced, if not controlled, by the effect of the iodide.

The iodide of potassium is used, in preference to the iodide of sodium, because of its more rapid absorption and its greater alkalinizing power.

Method of Treatment.—The following plan, with but trifling and immaterial modifications, is the one which I have pursued in all cases:

On the establishment of a diagnosis the patient immediately receives an initial dose of at least 10 to 15 grains of the iodide of potassium, which dose is increased by five or ten grains, according to the severity of the case, every two or three hours, day and night, and this is continued throughout the whole course of the disease, until defervescence is well established. However soft the pulse may become the dose is kept up, irrespective of the quantity which the patient is taking, the guide in our dosage being the regularity of the heart, as determined not by the pulse alone, as this may be irregular with a regularly acting heart, but by auscultation of the heart itself, and the character of the heart sounds, particularly of the second pulmonic sound; if this be clear and distinct, we are accomplishing what we desire. The left ventricle will take care of itself, in the vast majority of cases, if we look after the right heart. Should there be any irregularity of the heart itself, which I have rarely found to be the case when treatment was commenced early in the disease, strychnine is given in doses of $\frac{1}{60}$ to $\frac{1}{40}$ of a grain every four or six hours, until the heart becomes regular, being found sufficient to control the irregularity. The iodide was prescribed in a 50 per cent. solution, and was administered in milk, thus combining medication with nourishment, and necessitating less frequent disturbance of the patient. In this manner I have, in a large number of cases, given from 1,000 to 1,500 grains per day; in one case as high as 1,800 grains. Dr. H. T. Prentiss of Holyoke, Mass., reported to me a case in which he gave 3,000 grains daily for about four days, and another patient, a child, to whom he gave 2,100 grains daily for two days, with absolutely no signs of intolerance, and with recovery from the disease in both cases.

At the commencement of this plan of treatment a slight coryza occasionally appears, but rapidly disappears if the dose be pushed.

In cases in which the disease at its onset is accompanied by marked gastric disturbances I have combined with the iodide the aromatic spirit of ammonia. The use of this agent has been suggested by Sir James Paget as increasing the tolerance of the iodide.

If for any reason it were impossible to give the iodide by the mouth its administration per rectum would be indicated, or when this is not possible, or in extremely urgent cases, by subcutaneous injection. From experiments performed in the laboratory of Prof. William H. Park, to whom I am greatly indebted for advice as well as for the privileges accorded me, I have found that concentrated solutions (1:4) are well borne by rabbits, and do not seem to cause much pain. Occasionally when two drachms of this solution were injected, there was sloughing, but this was the exception, and the subcutaneous injections seemed to be well borne, both locally and generally. I would, however, suggest the deep muscular injection, when very concentrated solutions are necessary, as causing less pain, although subcutaneous injections are preferable, owing to their more rapid diffusion.

In treating the disease by this method, the fact cannot be emphasized too strongly that our guide in dosage must be the condition of the heart, i regularity, and the distinctness of the pulmon heart sounds. The quantity of the drug given p dose or per day must not concern us, our only co sideration being its effect on the heart. By this do not mean to infer that we can keep on indi criminately pouring down the iodide, without a reference to the quantity, but that we must governed entirely by the effect produced. I crease the dose rapidly and persist until the desi result is obtained.

This plan of treatment requires the same jud ment and circumspection in its administration are necessary in every other therapeutic measu From my experience and as a result of observatio on this large number of cases of my own and my c leagues, failure to obtain favorable results will attributable to faulty methods, and lack of cours rather than to ineffectiveness of the treatment.

In conclusion I desire to apologize for the complete and unsatisfactory character of this pap but the extreme prevalence of lobar pneumo the severity and unusually high mortality rate the disease at present existing, prompt me to earlier publication of this method of treatment th at first intended, in the hope that the results obtai by my colleagues and myself may be verified similarly favorable ones by the profession at la

After all, in the words of Prof. F. Riegel, "T ultimate aim of all medical action is to heal an help."

153 West Seventy-sixth Street.

REPORT OF A CASE OF KIDNEY DECAPS LATION, WITH SOME OBSERVATIONS O THE OPERATION.

By A. G. GRUNWELL, M.D.,
SURGEON U. S. NAVY.

The recent great interest taken by the profession large in the subject of the decapsulation of t kidneys in certain forms of disease of those org has prompted me to report this case operated up at the United States Naval Hospital, Washingt D. C.

As the subject is still a comparatively new one wi much about it still to be learned, I venture to co clude the report of the operation by a few rema as to what appear to me to be its possibilities and limitations.

The patient, a master-at-arms, third class, in t Navy, of very robust physique, was admitted to t hospital June 16, 1903, with the diagnosis of "Ne rolithiasis" on his hospital ticket, which also sta that the disease had existed certainly since Mar 14, 1903. As the hospital case paper gives a ve complete account of the case, I can do no better describing it than to copy from the entries made that record.

"Upon admission is suffering great pain, which referred to the region of the left kidney. He stat that the pain, in the beginning intermittent, is no constant, but that it is greatly increased in paroxysmal manner at intervals. He is well nour ished, but shows signs of continuous suffering.

"9.00 P.M. Has had two paroxysms of agonizin pain, over which morphia in safe doses has litt control. Chloroform inhalations afford relief for variable time. He has passed no urine sinc admission" (12.30 P.M.) "and vomits during th attacks of severe pain. The pain he describes as agonizing, and similar in character to most intens colic. It starts from the left kidney always, and extends down to the left testis, which retracts somewhat.

"June 17. Little change in his condition, except t during the day he has passed 800 c.c. of dark ne, which contains neither pus, sugar, blood, umin nor 'sand'; he has a troublesome diar-ea."

The case-paper entries from June 17 to 21, when was thoroughly prepared for operation, describe nptoms very similar to those just enumerated. e pain was practically constant, and at times so in-se as to make him cry out. Chloroform inhalations ne gave relief, and it was sometimes necessary to e them three or four times during the night. miting and diarrhœa were very prominent symp-ns, and on two occasions spasmodic twitchings, ompanied by intense headache or dizziness, gave impression that uræmia was not far removed. eyelids were "puffy," but there was little or no lling of the hands or feet, and no signs of cardiac ertrophy. The daily quantity of urine passed ied from 1055 c.c., the highest, to practically none the 18th, and the specific gravity from 1005 to . Albumin was nearly always absent, and n present occurred as a trace only, until the 18th, n the small quantity passed contained not only umin, but a substance which had the macro-pical appearance of pus. No blood was passed ny time. There was no fever, the temperature om going above 99° F. The diagnosis was never ain. It was believed that any one of the three ditions, stone in the kidney or ureter, wandering ney, or nephralgia, could account for the symptoms ent. The Röntgen rays gave no help, and the kness of the patient's abdominal walls made the lts of physical examination uncertain. The l absence of blood from the urine made the ence of a pelvic stone improbable, until the pearance of the urine containing the pus-like iment above referred to.

It was very difficult to make the stomach retain d of any kind, though every effort was made to ulate and build up the patient for the operation. as his condition was becoming daily more and re critical, it was decided on June 21 to prepare n for an operation on the following day. The ount of the operation is taken from his case-paper.

"June 22. Nephrotomy performed. Patient was sthetized with chloroform, and an incision, be-ning at the angle formed by the sacrolumbalis scle and the twelfth rib, and extending inward to e axillary line, was made. Without much diffi-ty and with little hemorrhage, the fat-capsule was ched. This was gone through with the fingers d the kidney found. It was necessary to remove rts of the fat mass surrounding the organ in order palpate freely the kidney, which was found to be atly enlarged, of a firm consistence, and of a dull, ty color, and so friable that when part of it was sped with a forceps to steady it, the substance re immediately, a dark hemorrhage ensuing. It s necessary to pack the wound and to wait a nute or two for bleeding to cease. Owing to the ge size and friability of the organ, it could not be wn into the wound, and was accordingly carefully cked around with gauze to hold it in position ile an incision was made into its substance from e cortex. Hemorrhage was profuse and of the me dark venous character, but could be readily ntrolled by inserting the finger. A probe was sed down into the pelvis, and the opening dilated the following finger, until the cavity of the pelvis uld be readily palpated. Neither pus nor a stone as found.

"At this stage signs of shock began to supervene, o the wound in the kidney was lightly packed with gauze, while the packing around the organ was renewed to retain it in place, presenting in the incision, until the danger from hemorrhage should pass. Bleeding had entirely ceased by the time the gauze packing was completed.

"The patient was put to bed and easily restored by ordinary methods. A liter of saline solution was injected into the rectum and retained. The pain from which he had been suffering, is due, beyond doubt, to a condition of intense venous congestion of the kidney."

All things considered, the patient passed the night following the operation very well, sleeping at intervals and being able to take and retain small quantities of nourishment toward morning. During the night he passed small quantities of urine containing blood, and in the morning 280 c.c. of coffee-colored urine was drawn by catheter. This urine contained blood-clots, showing that the ureter was probably free. He passed more urine during this, the first night after the operation, than during any previous night of his sojourn in the hospital.

As his condition was good on the morning of the 23d, it was decided to anæsthetize him with chloroform in order to dress the wound and at the same time to continue the operation and decapsulate the kidney. The following case-paper entry describes the operation:

"10 A.M. Wounds dressed under chloroform anæsthesia. At the same time, the patient's condition being good, the occasion was taken to complete the operation indicated, decapsulation of the left kidney. This was done without difficulty in the following manner: With a mouse-tooth forceps, the edge of the capsule was picked up where incised yesterday, and the incision through the capsule extended along the kidney until its two poles were reached, the capsule being split in a straight line. To do this it was first necessary to remove the most of yesterday's gauze packing.

"With the edge of the divided capsule held up by forceps, a blunt aneurysm needle was gently passed under its margin, freeing it from one end of the incision to the other. The opposite side was treated in a like manner, the incision extending the entire length of the kidney. First one margin of the freed capsule and then the other was now taken up with two dissecting forceps and rolled upon itself. Catgut sutures were passed through the rolls and through the adjacent lumbar fascia to which the kidney was thus anchored. This was done in order to bring the stripped organ into the wound, where it will be easy of access in case of secondary hemorrhage, as well as to give it a permanent fixed position so as to avoid subsequent dislodgement. The patient stood this little operation well, and the diminution in size and improved appearance of the kidney since yesterday was very great."

The gauze packing was all removed from about the kidney, only that extending down into its substance and a small amount placed on top of the organ to absorb blood or urine being left. The large wound through the skin and muscles was partially closed with silkworm gut sutures. He passed a comfortable afternoon, and toward night took and retained liquid nourishment and drank water freely. His evening temperature was 99° F, pulse 96, and respiration 36. Practically no shock followed this operation.

"June 24. Passed the most comfortable night (the second following the operation) since his admission, though tr. opii in ten-drop doses was given to him to keep him quiet. He complains, at times, of pain in the lower abdomen and also in the wound; though the agonizing paroxysms, with which he suffered prior to the operation, have ceased. The attacks of vomiting seem also to have ceased. In

the last twenty-four hours he has passed 1875 c.c. of urine, which is still 'smoky' but does not now contain blood-clots."

The analysis of the urine passed on the 24th was as follows: sp. gr. 1030, blood and albumin abundant, urea 3.28 per cent.

On June 25 the wound was redressed. Upon removing the gauze from the kidney substance a flow of blood was started necessitating the replacing of the plug of gauze. The urine secreted on the 25th amounted to 1480 c.c., contained albumin and blood, and was of the same high specific gravity. He was by this time resting quietly and all narcotics were withdrawn, though later it became necessary to give him an occasional dose of laudanum, for the reason that during his period of intense suffering, he had become almost an habitué of the drug. The intervals were steadily lengthened, however, and within a week he had received the last dose. From this time on improvement was steady, the desire for food and the ability to sleep promptly returning. The quantity of urine reached the normal within a week, but was subject to fluctuations, the diminutions being usually accompanied by attacks of pain and some nausea. These fluctuations, however, were always transitory, usually the next day the amount of urine reaching normal and the symptoms disappearing. The pain in the region of the wound was sometimes severe, but he described it as of a different character from the pain experienced prior to operation, and it was found that prompt emptying of the bowel frequently gave relief. The pain-free intervals steadily lengthened.

By July 5 all blood had disappeared from the urine and albumin was present only in traces, but it remained present until the first of September, when it had practically disappeared.

The large wound healed readily without the appearance of infection. During the first two weeks urine was discharged through the wound, but as the sinus narrowed it gradually disappeared.

On July 26 he was allowed to sit up, and during the last week in August he was given daily liberty to leave the hospital; throughout the month of September there were no unfavorable symptoms, and on October 7, at his own request, he was discharged to duty.

From experience gained in a single case, I feel some hesitancy in expressing my views as to the possibilities of this operation, but a careful study of the case and of the literature upon the subject, lead me to the following conclusions:

To those diseases of the kidney, such as stone, pyonephrosis, and "wandering kidney," long classed as surgical, certain forms of chronic nephritis must now also be added. Indeed the surgical treatment of this affection has already reached the stage where it is now clearly the surgeon's duty to operate in certain cases, for the operation cannot only be the means of saving the patient from a long period of suffering, but can save his life as well. Just where the limitations to operation are to be placed in this disease, is not yet clearly established, and much must be left to the judgment of the individual surgeon in selecting suitable cases, for the indiscriminate employment of the operation in all forms and stages of chronic nephritis cannot be otherwise than disastrous. That the operation itself is a severe one, apt to be followed by profound shock, is clear, so that the use of such a radical procedure should be a cautious one. At present I think it impossible for anyone to state exactly which cases should be operated upon and which should not, and conservatism will certainly give the best results in the end, for not only by proceeding in this wise will the ground be made sure of as it is gone over, but the limits of the operation will be gradually extended without the sacrifice of numerous lives which so frequently follows a new procedure rashly undertaken before its proper sphere of usefulness is defined.

In connection with this operation the whole field of nephritis should be studied and written anew. Especially from a surgical standpoint, much is yet to be learned about the etiology and the early stages of chronic nephritis, and until this disease is better known, allowing of an exact diagnosis being early arrived at, many persons must still die of it. What is true of so many other serious operations is certainly true of this one, viz., the earlier it is performed the more chance of success.

That there is a considerable period in the beginning of chronic nephritis when few characteristic symptoms are present and when the urine is almost uniformly albumin-free, there is no doubt. The anatomical conditions present can then be summed up under the head of "intense venous engorgement," and when the formation of cirrhotic tissue is not yet progressive. This stage lasts a variable time, often, I believe, much longer than is commonly supposed, but eventually it gives place to the stage of active disposition of new tissue, which contracting, forms the cirrhotic kidney. Possibly it may, though rarely, end in recovery, the cause of irritation being in some manner removed. The symptoms of this "stage of engorgement" are commonly ill-defined, the two most characteristic ones being pain and intermittent attacks of suppression of urine, either complete or partial. The combination of these two symptoms is very suggestive, especially if recurrent, and, I think, warrant at least an exploration. It is really deplorable that symptoms are not more pronounced in this stage of nephritis, for it is the one in which the operation of decapsulation would be least dangerous, and in which the best results are to be obtained.

How late in the disease the operation can be performed with a hope of success I am not prepared to say, but with our present knowledge the longer the disease has been established and the more extensive the cirrhosis formation is, the less chance I believe there is for success.

In an ordinary case of shrunken kidney of long standing when the subacute attacks of suppression of urine supervene, the patient's general condition being fair, I believe the operation should be cautiously tried, for it is not improbable that parts of the diseased kidney, which would eventually succumb to the general invasion, may be saved, and made to carry on sufficient work to save the patient's life.

How the operation produces its beneficial result is not yet certainly known. That the mere relief of congestion, allowing the over-distended veins to regain their equilibrium, plays an important part, is shown in this case, in which the relief from urgent symptoms was very prompt. However, there must be something more to make the beneficial result permanent. This is probably accomplished in two ways, (1) by allowing the kidney, when subsequently engorged, to swell beyond its capsule, thereby supplying an automatic relief from the vascular pressure, and (2) possibly by supplying new channels for carrying off the superfluous blood through the blood-vessels of the new-formed scar tissue, something after the manner of the establishment of an artificial collateral circulation in cirrhosis of the liver.

Relating to the technique of the operation, a few words may here be said: From my own limited experience, I do not believe that any one method of operating will apply equally to all cases with the

results. In some instances it is possible, and btless it would be the correct procedure to ve the capsule entirely from the kidney, but cannot be done safely in every case, I am rinced, as the organ is sometimes too large and friable to admit of the necessary manipulation out serious injury to the patient.

hat it is not always necessary to perform the tion upon both kidneys, at any rate simultaly, and probably not at all, I think this case conclusively. Neither is it necessary to lete the operation at a single sitting, and e decided shock, or where the patient is greatly itated prior to the operation, I believe it cerly better not to attempt it, but to limit the procedure to making the kidney readily ible, and to relieving the tension by a judicious on in the cortex, taking great care, however, e that the hemorrhage is completely con- before the wound is dressed and the patient ed from the table. The next day or the llowing, the decapsulation can be completed enough. The result obtained in my case nts me in recommending the method em- d, which is briefly as follows:

kidney being as freely exposed as possible ut serious injury to it and the surroundarts, is held in apposition to the wound reful gauze packing around and beneath o expose it freely, it may be necessary move some of the surrounding fat under re, or by the use of the angiotribe. An n through the capsule, extending the whole of the organ, along its convex surface, and round its ends or poles, using the finger as a , is made. One end of the divided capsule picked up with a mouse-tooth forceps and flat, blunt, curved instrument, like a blunt rysm needle, is passed beneath its margin, rating it from the kidney cortex. This separais carried out the whole length of the incision, the finger is substituted for the instrument the denudation carried down the side of the y as far as desired. By using two pairs of ps the stripped-up capsule can now be easily upon itself, until three or four rolls have been , or until the roll is at least half way down at side of the kidney, when three or four es can be passed through it and the adjacent ar fascia. The other side is treated in the way, with the result that the kidney is well ed of its capsule and at the same time is y enclosed in the wound.

e advantages of this operation are: (1) The t ease with which it can be performed as com- with the complete removal of the capsule. is no unimportant item where the condition e patient makes rapidity and the avoidance much handling of, or tension on, his kidney rative. (2) The kidney is fast in the wound, e it can be seen without difficulty and is ible in case of hemorrage, either immediate condary. As this method is also the best one dealing with a "floating kidney," the fixed ion of the organ is insured, so that it may at uture time wander from its bed.

efore the sutures through the capsule and the bar fascia are tied, the gauze packing must be arranged that it can be easily gotten out when ired. The wound should not be closed, but it be partially brought together, care being taken have an opening left down to the kidney, of cient size to allow of occasional inspection.

S. Naval Hospital, Washington, D. C.

CASES OF URETHRAL STRICTURE AND THEIR MANAGEMENT.*

By JAMES PEDERSEN, M.D.,
NEW YORK.

ADJUNCT PROFESSOR OF VENEREAL AND GENITOURINARY SURGERY, N. Y. POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; FELLOW N. Y. ACADEMY OF MEDICINE, ETC.

The following reports, compiled from my office and hospital notes, exemplify some of the phases and complications of urethral stricture, and describe the management that seemed appropriate to each individual case. The term "management" has been used advisedly, implying that the "treatment of stricture," in its literal acceptation, forms but a part of what is necessary to secure to the patient the best ultimate result.

Case I will illustrate the management of a stricture of small caliber complicated by an acute specific urethritis. Incidentally it presents a typical if not the normal course of such a urethritis in a healthy, intelligent man.

W., age thirty-nine, married, presented at the office with a urethral discharge, a sense of irritation in the deep urethra, and slight frequency and urgency of urination. At night he was obliged to urinate twice. He had had two previous attacks of urethritis; respectively nineteen and fourteen years before. The second left a stricture which was dilated to 28 F. by his surgeon. The patient was then taught to pass a sound; but he neglected to do so until retention threatened. He then resumed gradual dilatation on his own account, beginning with No. 16 F. He carried it up to 20 F., after which he passed a sound only at intervals. At the time he contracted the urethritis for which he now sought relief, he had not passed his sound in two months.

Examination revealed all the evidences of a virulent infection with severe inflammation. The prostate was normal, except for tenderness in the median line. At this time no gonococci were found. A urinary antiseptic was prescribed and he was directed to drink water freely between meals, to remain recumbent, to wear a suspensory, to take three hot sitz-baths daily, and twice daily to flush the urethra with a warm 1-30,000 solution of bichloride of mercury, using a quarter-ounce hand-syringe. His use of alcoholics, tobacco, and coffee was regulated.

The anterior urethritis began to subside at once; but the acute posterior urethritis ran the usual course of a mild inflammation in this region. By the tenth day the patient was almost free from the sense of irritation, and the urinary intervals were nearly normal. No attempt was made to arrest or to modify the acute posterior urethritis because of the patient's hypersensitiveness and fear of instrumentation, and because the inflammation was of that mild grade which requires no intervention. Many gonococci were now found. By the fourteenth day the discharge had begun to diminish. The prostate remained uninvolved.

On the twentieth day the subacute stage having set in, the urotropin was replaced by a balsam. Sitz-baths were continued for a few days longer to minimize any congestion about the stricture. To the same end the warm hand-injection was only gradually withdrawn and replaced by an astringent. At the close of the fifth week there remained only a glairy morning drop and the urinary intervals were normal. The urine was clear, but contained many shreds. All liability to retention having passed, the patient was sent away for two weeks with instructions to use his hand-injection of bichloride, if necessary. The necessity arose but once—after ex-

*Read before the Genitourinary Section of the New York Academy of Medicine.

posure to cold and wet followed by whiskey. A mucoid discharge reappeared, but promptly disappeared under the injection. The urine, however, had again become clouded.

As the urethra evidently was still susceptible, dilatation was postponed another fortnight. It was then begun with his own 18 F. sound, which he succeeded in passing after a little manipulation under supervision. There are no skill and gentleness equal to those of the patient himself once he has practised the technique and learned the peculiarities of his urethra. In this particular case I believe it was good management, not only to let the patient make the initial attempt (under supervision), but also to allow him the instrument he was accustomed to, in spite of its caliber, which was dangerously small for use in a recently inflamed, strictured urethra. The instrumentation was followed by copious irrigation of the penile urethra from the meatus.

The only reaction was a trifling increase in the discharge, which his hand-injection promptly arrested. At the end of a week the dilatation was carried to 20 F. Six days later, sounds 20 F and 22 F. were passed with the utmost care and gentleness. Nevertheless, a little blood appeared at the meatus. The usual after-irrigation was therefore employed. He was now free from all urethral irritation and the urine had become almost clear.

The stricture's caliber having been restored to 20 F., with which the patient had always been satisfied, he now considered himself cured and stopped treatment, contrary to advice.

To explain certain details in the management of this case it should be stated that the patient was first directed to flush or "irrigate" his urethra with a solution as hot as he could comfortably bear because of the highly inflamed condition, and that the flushing was continued long after the primary indication had ceased because of the susceptibility of his urethra. Furthermore, he was fastidious, apprehensive, and possessed of preconceived notions. Of astringents in general, and silver nitrate in particular, he had an unconquerable dread that was not without some foundation in fact, judging from his decription of the treatment given him in the first instance, fourteen years before.

CASE II will illustrate one possible management of an irritable and somewhat resilient stricture, which, theoretically, often requires urethrotomy.

P., age thirty-five, married. In May, 1900, he entered Bellevue Hospital with retention of urine due to a contracted organic stricture in the upper bulbous region. This was relieved with filiform guide and tunnelled catheter, after which, gradual dilatation, accompanied by irrigation of the penile urethra from the meatus, was begun. The first three dilatations were followed by a urethral chill; on one occasion spasmodic retention occurred. At the end of two weeks, the stricture having become sufficiently dilated to render a recurrence of retention unlikely, he was allowed to leave the hospital and to come to the office for treatment. In preparation he was given quinine, three grains three times daily for two days. The technique of the dilatation was as follows: Copious irrigation of the penile urethra from the meatus with a solution of 1 to 30,000 bichloride of mercury; then distention of the penile urethra with iodofom oil; then the instrumentation; finally, irrigation of the penile urethra again. First, Banks' dilating filiform bougies were used; then flexible bougies until 16 F. could be passed with ease; then sounds. Thus, at four-day intervals, the caliber was gradually increased until, on the occasion of the fourth dilatation at the office, sound 20 F. could be pas to the bladder. No urethral chill followed th dilatations at the office, nor hemorrhage, excep the second when a drop of blood appeared at meatus. At the fourth dilatation the qui was discontinued on trial; but feeling hi threatened with a chill three days later, he sumed it according to orders. It was conti for a few weeks after this.

Irrigations before and after were now discontin but sterile iodoform oil remained the lubric At the seventh dilatation, one month after left the hospital, a 24 F. bougie was passed. was followed by a slight stain of blood, an ins tion of silver was given in the form of a 1-per solution of protargol—it being less irritating the nitrate. The patient now went abroad for summer.

He returned three months later, having been and free from urethral symptoms. Explor showed a recontraction to 16 F. Quinine wa scribed and dilatation was resumed by the technique as originally. In spite of all, he a chill after the second dilatation of this co Furthermore, the stricture increased in irritab as shown by the tendency to urethral spasm a time of instrumentation. This irritability met by the topical use of protargol first, then nitrate, combined with dilatation at interv one week, the urine being kept bland mean His final chill occurred at this time, during usual congestion of the urethra. As befor seventh dilatation carried the caliber up to 2

The same general management was followed 27 F. was reached. He was then taught to pa sound. For a period he did so once a week porting at progressively longer intervals for in tion and treatment. While the size of the s was gradually increased the frequency of its us decreased until, a month before the end of the se year, he was passing 29 F. every third week wit reaction, and without other precaution than dinary asepsis.

This rate was continued for six and one months, when the sound was tentatively di tinued, one year ago. Neither recontraction irritability has developed, as proven by repe examinations at intervals. The latest was six days ago. From the day he left the hos he attended to his business without interruptio

The next two cases are reported somewha detail because of the important and intere complications they present.

CASE III is one of tight stricture, chronic titis and recurring epididymitis.

G., age thirty-one, married, presented with the tory of tight stricture of long standing, and ad that whenever dilatation had been undertaken, incapacitating epididymitis had either threatene occurred. The left epididymitis had been infla once; the right, three times. As a consequence had never persevered in any course of treatm Once epididymitis had developed independe of any instrumentation. Though liable to re tion, he was most reluctant to have any tr ment begun. The symptoms were a small stre a sense of "tightness" in the urethra when uri ing; a straining to urinate; a milky morning dr bloody semen, and a continuous lumbar ac No nocturnal urination. The diurnal interv were from four to five hours; occasionally, he periods of diurnal frequency, unaccountable exc by supposing an irrigating urine; a transient acerbation of the urethrocystitis, or the prese

a calculus. He had had urethritis once, fourteen rs before. There was no history of traumatism. he two-glass test showed equally cloudy, faintly moniacal urine and many shreds. This bad lity, the history of recurring epididymitis, and importance of reassuring the patient, made it d management to confine the first instrumenta- to a cursory examination of the penile urethra, to occupy a few days in improving the urine preparing the urethra for the detailed explora- and subsequent treatment. A tight stricture he bulbous portion and general hyperæsthesia he urethral mucous membrane were found. patient was instructed how to use a hand-injec- of a warm solution of bichloride of mercury o,ooo) twice daily, and a urinary antiseptic y three hours was ordered. He was warned st the usual causes of retention. Fortunately abits as to alcohol, tobacco, and coffee were tionally good.

er five days of this preparation the penile ra was irrigated copiously and distended iodoform oil, a filiform bougie introduced, ver it a 12 F. tunnelled catheter was passed to ladder. Two ounces of turbid residual urine evacuated, and two and one-half ounces of a solution of silver nitrate (1–3,000) were instilled into the bladder and left. Tun- sounds 14 and 16 F., in turn, were next threaded filiform and passed to the bladder. This leted the first dilatation. Irrigation of the urethra was repeated, massage of the pros- performed, and the patient allowed to void the nitrate solution that had been left in the er. The hand-injection and the cystogen continued; in addition he was directed to take t sitz-bath three times daily and to keep is feet as much as possible. He remained mbent more or less for three days, then left city on business, and ten days elapsed before could present himself again, at which time as able to report that his backache had dis- ared, that urination required less effort and comparatively comfortable, and that he had no symptom of the dreaded epididymitis.

true recontraction, however, had taken place. rdingly the previous dilatation up to 16 F. repeated. Four days later it was possible troduce a 12 F. natural curve web catheter the purpose of preparing the bladder *before* eeding with the dilatation, and tunnelled d 14 F. entered so easily that it was permis- e to follow it by No. 18 without the intermediate

ilatation now proceeded at intervals of from days to two weeks, depending upon his im- tive business engagements out of the city. two or three occasions it was omitted, and only ation of the bladder and massage of the prostate performed because of a suspicious ache in or the other groin. At the end of five months, n preceded by sound, 23 F., 24 F. could be d to the bladder easily and with very slight mfort to the patient; the residual urine had inished to only half an ounce; its turbidity slight; its odor normal. No hemorrhage had n excited. Epididymitis had not occurred.

he strictures (subsequently a second one was d at the bulbomembranous junction) are y rigid and unyielding. This fact, together the unavoidable irregularity of the visits ong intervals, accounts in part for the relatively progress. Under eucaine anæsthesia the dila- on probably could have been carried a point her at each sitting. This was not practised, it being preferable in such a case as this to have the patient's sensations assist in deciding the permissible degree of dilatation. So long as he had a stricture offering any appreciable obstruction to the urinary stream, and a posterior urethritis of sufficient grade to cloud the urine, just so long would he be liable to recurring epididymitis, one exciting cause of which would be an overdilatation. The prime object was to remove the risk without precipitating the accident.

I regret that in this I was not successful. Four months later, when the caliber had reached 26 F., his first epididymitis developed during a period of turbid urine, the result of errors in diet to which he was prone, and immediately after repeated violent exercise, followed by a jarring of the testicle. There had been no instrumentation for eight days. After steady progress for another four months, during which his urine was brought to an almost normal quality, though his visits had been somewhat irregular, a second epididymitis developed under similar conditions, fourteen days after instrumentation. A month later he broke down from overwork, too frequent coitus and violent exercise. This was promptly followed by a relapse of his old-time intermittent fever with hæmaturia. It yielded to quinine as before. There was frequency for a few days.

He was then sent on a vacation. On his return tentative dilatation was resumed. It resulted directly in his third epididymitis. After a second period of rest his health began to improve, and aided by free diuresis his urine returned to normal.

The Oberländer dilator was now substituted for the sound with apparent benefit, but following the use of a 1–1000 silver nitrate solution in the bladder the fourth epididymitis developed directly. Dilatation was thereupon discontinued and argyrol solution, 5 per cent., was substitued for the silver nitrate in the effort to further improve the bladder and posterior urethra before resuming dilatation again. He is under this treatment at present.

Owing to the patient's size and to the rigidity of his perineum, the massaging finger with difficulty reaches the limits of the prostate. Nevertheless massage of the prostate has been repeated after every dilatation, not only to reduce the congestion of the prostate body, but also to express into the prostatic urethra any inflammatory products that may have been pressed into the ejaculatory ducts by the instrumentation, and to have the same swept thence by the silver solution left in the bladder and voided for that purpose at the completion of each dilatation.

Case IV, one of traumatic rupture of the urethra, details the management of a post-operative filiform stricture with a perineal urinary fistula.

H., age forty-nine, single. In jumping from a moderate height he struck on a post and sustained a complete rupture of the urethra. Apparently the gravity of the condition was not recognized; when seen by a consultant forty-eight hours after the accident the extravasation of urine had become extreme. As described to me by the patient, three operations followed: The first, performed forty-eight hours after the accident, liberated the extravasated urine and established bladder drainage; the second, performed two weeks later, reunited the severed urethra; the third, six months later, was to close a urethral fistula that remained. As is not uncommon, this failed of complete success. Through some misunderstanding the after-treatment was discontinued, and the patient was left with a sinus leading from the deep urethra and bulb to a point in the perineoscrotal region, and

with a dense, tortuous stricture at the corresponding point in the urethra. Through the sinus urine leaked continuously, and with every urination a quantity would escape under pressure while only a dribbling stream escaped at the meatus. The patient was compelled to wear a perineal pad and to change it and his underclothes many times a day. Altogether his condition was pitiable, and had profoundly affected his health and spirits. For the relief of this condition he presented himself one year after the accident.

Examination showed the condition as described. The urine, however, was bright, clear, and contained only a very few shreds. After preparing the urethra, a filiform was with difficulty wormed through the tortuous stricture into the bladder. On this, tunnelled catheter No. 9 F. was threaded and passed to the bladder by gentle manipulation. Moderate hemorrhage was excited. Tunnelled sound No. 11 F. completed the first dilatation. The unyielding nature of the stricture and the patient's worn-out, hyperæsthetic condition, made strict conservatism desirable. All instrumentation, however gentle, caused considerable suffering. Local anæsthesia could not be taken advantage of, as the anæsthetizing solution escaped through the sinus as fast as it was injected at the meatus. After a final irrigation of the urethra the patient was sent home to rest as much as possible and to take a hot sitz-bath three times daily. A urinary antiseptic was prescribed.

Four days later (his second visit) he reported that he had suffered no reaction, and that the stream from the meatus was stronger The dilatation at this sitting was effected by the filiform guide and tunnelled instruments Nos. 9, 12, 14, and 16 F. Barely more than a tinge of blood followed. The usual irrigation of the urethra, before and after, was performed. That evening retention of urine occurred. Apparently it was due, in part, to urethral spasm; it was easily relieved with a soft rubber catheter by his physician. Decided improvement was now noticed. He could void urine without effort; there was less leakage from the sinus; one perineal pad a day was sufficient.

Five days later (his third visit), a preliminary stretching was given the entrance of the strictured zone with the conical tip of a 23 F. flexible bougie. The dilatation was completed with filiform and tunnelled sounds beginning with 14 F. and ending with 20 F. For the first time there was more than moderate hemorrhage. Therefore, when irrigating the penile urethra, about two ounces of the fluid were made to flow into the bladder from the meatus, after which the patient stood up and voided the fluid.

On the fifteenth day the sinus closed. To favor it, and because of the hemorrhage excited by the third dilatation, no increase of the caliber was attempted until the sixth dilatation, sixteen days later, when 22 F. was reached. Though vcy carefully passed, it caused an immediate reopening of the sinus.

For the next four months it was alternately open and closed. Every passage of plain steel sounds at intervals of one week while raising the caliber of the stricture from 22 F. to 25 F. caused the sinus to leak a little for a few days. After a most cautious and gradual dilatation to 27 F. with a Kollmann dilator, the sinus leaked a great deal.

The indications were plain for more conservative dilatation of the stricture, and coincident stimulation of the urethral mucous membrane with silver nitrate solutions. Accordingly the patient was taught to pass sound 24 F. and later 25 F. once a week, after which the topical treatment of the urethra was carried out with endoscope, syringe-sound, catheter.

Meanwhile the involuntary, continuous leak from the sinus had gradually ceased; urine esca from it now only during urination. When he become expert with sound 25 F., he was directe pass it every five days and to come for top treatment and further dilatation every two we On two of these occasions the Kollmann dilator used, but never opened beyond 28 F. Later he given sound 27 F. to pass once a week. The s now allowed only a drop to escape during urinat and in the course of the twenty-first week it cl permanently. Long before this he had recov his health and had resumed business.

A few months later he was passing 28 F. e once a week and reporting at the office every weeks. His urination was normal. The urine tained only a few flakes with slight excess of mu After he had been passing 28 F. only once every days for awhile, he ceased reporting monthly usual, apparently well satisfied with his conditio

The comment may be added that topical t ment every two weeks should have been conti awhile longer in such a case; but the patient f it inconvenient to come to the city regularly.

Case V is one of recontraction following a lected urethrotomy.

B., age forty, married. He was referred to m June 22, 1901, complaining of an inability to ur except in drops. This condition had exist month. He had had urethritis only twice, the fifteen years before. With both, severe ch In 1884 he was thrown astride the limb of a tre neither hemorrhage nor dysuria followed. years later he had acute retention for which a neal section and urethrotomy were perfor There was no after-treatment and he failed to the sound with which he had been provided. T since then he had had retention, to relieve whi had catheterized himself with an English web, etted catheter of small caliber. He declared passed it without producing any hemorrhage. alcoholic habit was fairly marked.

Examination showed a filiform stricture situ toward the upper limit of the bulbous portion. the usual technique a filiform was passed to bladder. The smallest tunneled catheter wa rested. First proving that the instrument wa structed and not held by the swelling of the fil within the necessarily narrow tunnel, a B bougie was substituted and the stricture dila very little. After the urethra had been irri again he was sent home to take a hot sitz-ba once, to go back to bed and to use hot applica locally. By the following day a slight recontra had taken place. He was still able to urina stream, however. A copious urethral irrigatio warm as he could bear, was given, and he wa structed to use a hand-injection twice daily of a solution of boric acid. The third day a second tempt to dilate the stricture was made. The lu was not found as easily as on the first occasion, the somewhat prolonged instrumentation ca increased swelling in the stricture. As a co quence, the following afternoon, he developed re tion which had to be relieved by passing Ba bougie and leaving it in place for five minu Immediately thereafter he voided urine in a g stream. The urethra was irrigated before and af as usual.

It having become evident that serious reten might occur before dilatation could succeed, patient was sent into the hospital at once for op tion. It was to be expected that preparatory

n bed and systematic irrigation of the penile rethra for three days would relieve the congestion out the stricture and allow the tunneled catheter pass. Owing to a misunderstanding the irrigaıns were not carried out, and the stricture reined impassable to the metal instrument at the ne of operation. I therefore cut down through the b upon the tip of the instrument at the face of the icture. With a slender probe-pointed knife, the nen was enlarged until it would admit a thin, oved director along the filiform guide. The throtomy was then completed to 30 F., with toury and Otis urethrotome.

Twenty-four hours later the urethra was irrigated d sound 28 F. was passed until it encountered the ineal tube. The bladder was irrigated daily. the third day the perineal tube was removed manently; the bladder being healthy did not deıd longer drainage. At the same time a 30 F nd was passed through the whole length of the thra. This was repeated five days later. The ineal wound had closed by the seventh day. The ient left the hospital on the thirteenth day and orted at the office.

s is not unusual early in the after-treatment, a ht degree of narrowing was noted at this time. rthermore, the configuration was such that the nt of the sound had to be deflected before it ld pass smoothly onward to the bladder. From date the management consisted of the usual ual dilatation at weekly intervals to restore the ber, and of instillations of silver nitrate by means he Bangs' syringe-sound, alternating with apations through the endoscope, occasionally comed with a silver nitrate irrigation of the bladder. the end of two weeks, the caliber was again 30 F.; incisions in the urethra had healed, as shown by absence of blood after instrumentation; the asional slight incontinence of which he had comined after leaving the hospital had ceased, and urine presented only a few flakes. Having own before how to pass a sound for himself, he s easily re-instructed. On September 10 he was liged to leave the city. His instructions were to his sound once every two weeks.

He reappeared December 5 in bad condition, sically and mentally, the result of hard drinking d neglect to pass his sound for about two months. vertheless, the urinary function was normal and urine contained only a very few light shreds. amination showed a recontraction to 24 F.; but r sound 24 F. had been passed, 26 F. followed h fair ease. This instrumentation, however, was icient to re-awaken enough posterior urethritis d urethrocystitis to give him cloudy urine again. o bladder irrigations with 1-1000 solution of ver nitrate four days apart were corrective. thin two weeks he was again passing a full-size nd at proper intervals; but he continued drink- and soon disappeared from observation.

Case VI is typical of stricture of large caliber h secondary posterior urethritis and urethroitis due to a combination of causes: An anteced- urethritis, the stricture itself, excessive use of bacco and coffee, lithuria, and the practice of thdrawal in which the patient had indulged three nes a week ever since marriage three years before. F., age twenty-six, married, came to the office mplaining of very frequent and painful urination. e was compelled to rise at night every half hour. hortly after marriage he developed a mild urethritis, terior and posterior. Since then there had been sense of uneasiness during urination. With this ception he had enjoyed average general health ntil two months before, when he began to urinate with gradually increasing frequency. At one time urination occurred every fifteen minutes accompanied by pain referred to the vesical neck. Any jolting increased the bladder pain. A month later blood appeared in the urine; but under rest in bed and irrigation of the bladder this ceased in about a week. From time to time he had gone to bed, and had been variously treated for cystitis, vesical calculus, and prostatitis. He had resorted to morphine suppositories. There was neither a personal nor a family history of tuberculosis. By nature neurotic he had now become neurasthenic. He was an abstainer from alcohol, but an inveterate smoker; his habit as to coffee was two cups three times a day.

On examination he strained to produce a stream, and then suffered severe tenesmus. The urine was opaque with phosphates and pus. The symptom-complex was so suggestive of vesical calculus that I persuaded him to let me search his bladder.

After excluding acute prostatitis, the penile urethra was irrigated, anæsthetized, and moderately distended with iodoform oil. A small soft rubber catheter was very slowly passed to the bladder. Even the gentlest irrigation was painful; the bladder could tolerate only two and one-half ounces. Nevertheless, with a Thompson searcher as thorough an examination as possible was made. No calculus was detected.

He was put to bed and on fluid diet, chiefly milk, the free use of plain water, and urinary antiseptics. Very gentle irrigation of the bladder from the meatus once daily with a warm solution of boric acid was carried out, the penile urethra previously anæsthetized. He began to improve at once and dispensed with his morphine suppositories. By the fourth day he was rising only every two hours at night, and could retain four ounces of urine at a time during the day. The quality of the urine had greatly improved.

Under local anæsthesia an instillation was now attempted with a 20 F. soft rubber catheter. It was obstructed at the bulbomembranous junction. Prolonged instrumentation being contraindicated, a bladder-irrigation from the meatus was given instead. The following day a *smaller* catheter was introduced easily, and a one per cent. solution of protargol instilled.

Three days later, the bladder tolerating seven ounces, cystoscopy under local anæsthesia was performed. The mucous membrane in general was fairly normal; the trigone was congested. No calculus was seen. As a final proof, a 22 F. evacuating tube was introduced and the bladder carefully pumped. The stricture at the bulbomembranous junction was then gently dilated to 26 F., after which the bladder and the urethra were flushed by catheter and a 1-per-cent. protargol solution.

No reaction followed the instrumentation; he was allowed up the following day. His diurnal urinary intervals were now from two to three hours; probably they would have been longer but for the prescribed diluent. At night he had to urinate but once. Four days later (on the twelfth day) he left the house and reported at the office. The urine now showed many shreds in the first glass, but only an excess of mucus in the second. Endoscopic examination of the membranous urethra showed acute hyperæmia; at the bulbomembranous junction the mucous membrane had a swollen, thickened appearance and bled slightly; the bulb presented congestion. Silver nitrate solution, five grains to the ounce, was applied.

At the end of another week he did not have to

rise at all at night. The urine showed a few shreds in the first glass, the second was clear. A combined dilatation and instillation of a 1–1000 solution of silver nitrate by means of a 26 F. Bangs' syringe-sound was given. It was repeated at weekly intervals twice, and again at the end of two weeks. Three weeks after this he was entirely free from the long-standing urethral irritability. He was asked to report every two months for inspection.

CASE VII is one of chronic extravasation of urine with scrotal abscess and urinary fistula. Incidentally it illustrates the reparative power of the urethra.

C., fifty-nine, married, was admitted to my service at the Post-Graduate Hospital June 30, 1903, complaining of long-standing dysuria and of a scrotal abscess that had developed about four months before. It had twice been incised and more or less completely drained. His health had failed; finally he had to give up work.

Examination showed extreme hyperæsthesia, a filiform stricture in the midzone of the penile portion, and a foul, sloughing sinus in the right half of the scrotum, which in turn was much inflamed and tumefied. Near the root of the penis the abscess had a small upper opening, from which a few drops of urine escaped during urination, while from the large lower opening it came in a free stream. The patient was poorly nourished and in bad general condition. He was slightly septic and uræmic.

After two days of rest in bed and preparation, an ordinary external urethrotomy was performed by the usual technique. The stricture was divided to 30 F. with the Otis urethrotome. A length of soft rubber catheter was tied in the penile urethra to act as a splint, that the opening between the urethra and the sinus might be allowed to close properly by granulaton. The scrotal sinus was treated by dissecting away all the old cicatricial tissue from the lower opening after both it and the upper opening had been enlarged, and by thorough curetting. Through and through drainage was established.

On the fifth day the catheter-splint was removed from the urethra and very gentle irrigation from the meatus was performed once daily. No fluid escaped by way of the sinus; the communication proved to have closed permanently. The bladder was irrigated once daily by way of the perineal tube, which was removed, sterilized and reinserted at proper intervals up to the tenth day, when it was left out. The perineal wound healed slowly; by the end of the fourth week it had closed permanently.

For obvious reasons a sound of small caliber, 22 F., was the first one used after the operation. This was on the tenth day. It passed smoothly and was repeated a few days later. On the seventeenth day it was repeated and the bladder irrigated with two ounces of a 1–1000 silver nitrate solution, the urine not being satisfactory. Following this the bladder was irrigated with boric solution once daily, but owing to a misunderstanding of the order was distended to its capacity.

The patient now developed an irregular temperature, ranging from 99° F. to 104° F., apparently due to the lighting up of an old pyelitis or an absorption focus in one or the other kidney. All local treatment was therefore discontinued. Under free diuresis (up to six quarts of water a day), the administration of stimulants, urinary antiseptics, and creosote, the fever ran its course in about three weeks.

Two weeks later the after-treatment of the urethra and bladder was resumed. He has progressively improved in health and strength, and has returned to his business. At present, sound 23 F. can b passed with ease; the bladder function is good a the urine is fairly clear. The scrotal sinus has r mained closed, as has also the perineal wound.

A summary follows of certain details in t technique: Copious irrigation of the penile urethr from the meatus with a solution as warm as t patient can bear, is advised before and after i strumentation until the stricture has been dilat beyond the danger of retention from reaction swelling. The irrigating solution should be deli ered under gentle pressure from a hand-syrin with separate blunt tip. Similar irrigation, or instillation or irrigation of silver nitrate, protar or argyrol, is to be practised whenever blood a pears after instrumentation.

To facilitate the passage of small instrumen especially filiform bougies, and for asepsis. penile urethra is moderately distended with a per-cent. solution of iodoform in sterile sweet almo oil or with plain sterile oil.

The filiform guide and tunnelled instruments dispensed with as soon as a 20 F. ordinary so can be passed to the bladder with fair ease. E ceptionally the filiform guide may be dispen with at 18 F.; but, if the canal through the st ture is tortuous, or if there is a pocket or an false passage, a sound of small caliber than 20 unless very blunt, is dangerous except in ski hands.

The bladder is treated so long as there is evid of cystitis or urethrocystitis.

Specific treatment of the urethral mucous m brane with silver nitrate solutions is begun as s as a caliber of 18 or 20 F. has been reached, is continued combined with dilatation, until tissues have been made as near normal as poss under the conditions present.

At the conclusion of the after-treatment lowing urethrotomy, the patient should report fixed intervals for two years that any tendency recontraction may be detected and met, and t if he is required to pass a sound, the proper li tations thereto may be prescribed.

20 EAST FORTY-SIXTH STREET.

SOME OBSERVATIONS WHILE SERVING THE PHILIPPINES.

BY J. A. GUTHRIE, M.D.,
SURGEON, U. S. NAVY.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ASSOCIATION MILITARY SURGEONS, ETC.

THERE are few "first comers" to the Philippines do not believe that all they see, the air, water, so in fact the whole earth, with its many and sundry cumbrances (living and dead)—is reeking in ger I do not except the medical man entirely in this tiatory impression, because I have heard one or of them make some startling statements tending ward my partial conclusion. This idea, however, l but a short time with the common-sense practitio for he soon settles down to ferret out a real etiol of disease, abounding within these our new pos sions. Not so with his lay brother, who has contract along with his "philippinitis," "germ-mania." thinks the islands full of germs, and tells everyone Once I asked an acquaintance why he objected a certain recently built house located in Cavite, which he replied, very promptly, that he knew was "full of germs." I inquired his reason for s an assertion, whereupon he vociferously respond "Why, I saw a cockroach in this house over inch long."

The microscope is a good diagnostican in so cases and in some hands; but when the egoist ta

ld it is time for the laity to watch out for him; much so, as they would an inexperienced boy ndling a shot-gun; it is he who instilled my end. There is still another sort, a professional, o imbues into the minds of men a mistaken tion regarding germs; he is of a more intelligent ide, and consequently more dangerous to human- —especially those poor unfortunates doomed to in the Philippines, and at this minute battling inst the heat of the tropics. These alarmists are ponsible for all such cockroach episodes. They , in a large percentage of cases, seeking notoriety h a microscope. He carries it under his arm it were, and never ceases to talk of it, telling n or Jim all about his new discoveries with it, vely explaining its workings the while. We et him, even out here in the Philippines, spec- ing into the remote corners of these islands of s, advocating a thousand new methods as to the "X" bug may be destroyed, etc. So rely dissimilar is the strenuous surgeon and sician, with rolled sleeve and bared arm, mod- y working, working on a common-sense principle the good of those sufferers most in need of his gies—the latter certainly does more for advance- t, especially so in this newly born colony where there is a bit of fighting going on, with ladrones). r things are more settled, there is ample time the germologist. In lenience toward his mis- lied energy, however, even while there are roscopic topics of more consequence, let us rse him to the extent that we trust he will e day catch his germ, and pin it fast to his terfly-case, hoping posterity shall be benefited o doing. My plea is not against the microscope, her, I wish to leave it in expert hands. If there those who have been sent to do microscopic k alone, let them do it and not neglect something t they are familiar with, for the sake of dab- g in another man's work —let every man stick his original job.

It is the opinion of many that skin diseases deserve most thought from professionals serving in the ilippines. It is useless to attempt an enum- tion of all the names given to each by various thorities (many of whom differ so widely). To cuss them *tout ensemble*, without classification, l bring out my observations just as clear. The an of life designated as the skin, but which is erally thought to be a mere covering not unlike clothing, even by not a few well-educated per- s, is taxed to its utmost in this climate, not only ause of the tropic heat, but because of many ditions of living here. The Philippine sun ms to have a powerful influence upon the body, overstimulating effect, likened to the surcharged inic ray, penetrating the skin along the nerve rs, and exerting its influence upon the entire vous system. I am of the opinion the sun's s exert this influence more in the region of the ilippine Islands than in any other tropic country the world; because, for one thing, we do not as accommodate ourselves to our environment. e do not dress properly, we do not bathe our dies systematically, we do not cool our houses we should (owing no doubt to the unsettled te of affairs), and most of us eat and drink properly. I repeat, that many think, other an a protection to the flesh, blood-vessels, nerves bones, the skin could be dispensed with, parch- ent or canvas answering the same purpose. No e outside of a medical graduate thinks of the kin as a vital organ of life. I would be pleased to emonstrate to some of these the dangers of remov- ing more than one-fourth of their cuticular cover- ing, only I refrain from annoying my conscience to that extent and become responsible for life. It ought to be, if it is not, well known, how- ever, especially in our great cities, where fires are not infrequent, that extensive burns destroying large areas of skin always prove fatal. Now it is not necessary to destroy entirely an organ to dis- able the human economy. If we weaken a vital organ, all the remaining machinery of the human system suffers in proportion. The skin is disabled in the Philippines, hence most of the nervous troubles. What is to be done when an organ is disabled, and is all the while subjected to the same disabling influence: this is a pertinent query. I should suggest very great care and nursing of the organ; pamper it, and do not expect more of it than God Almighty intended. If we white-skinned races expose our bodies unduly—(for we are taught in childhood about white surfaces that blister and black ones that do not)—overstimulating our circulation artificially at the same time, and do not wash off the greater output from the sweat glands, we make this part of the machinery do extra work under the most unfavorable con- ditions. This injustice to a thermic regulating, breathing organ will cause more trouble than if a small part were torn off, entirely exposing the flesh, blood-vessels, nerves, and all the delicate structures beneath. A covering is sufficient to protect these; but when we remove a covering possessed of vitalizing functions, the great harm comes from this loss, and not because of undue severity to the structures beneath. The under- lying tissues can be artificially protected from harm, but the function of the working covering is lost forever, and so what remains must do extra work. Such a state corresponds with an active regiment. Kill off a third, or make the whole inefficient by overwork, and you get bad results in either case. The glands of the skin are the individuals in the regiment. Weaken the individuals, and the regi- ment deteriorates as a whole.

Not only in guarding our skins have we to con- tend against the sun's rays in all its forcefulness as an agent arrayed against these glands, causing inflammations of every description, but insects prevail in vast quantities; their stings and bites add to the enemy's strength, and so we must prepare against many foes, and toughen the point of first attack. Here are found insects in choice assort- ments, centipedes, spiders, scorpions, and the fes- tive mosquito in his glory. The reptile family I shall not mention, and yet there is a healthy pro- portion of these as in all tropical countries. Even after months of residence in the Philippines, when one has become acclimated to the singular potency manifested by this influence of sun, there is in reserve an array of living things to prey upon the poor alien's depleted cuticle.

Investigating the cause of that sudden exhaustion seen in our marines during the Samar campaign, I discovered that most of the cases of "giving up" (as they called it) on the march was due to a species of land leech. This blood-sucking animal would fasten itself to the bodies of our men while they were asleep, or even while they were walking along the trails (as there was little or no pain experienced when this occurred). It would attach itself to their legs unbeknown, and carry on its depleting influ- ence silently though seriously to the unfortunate victim. The fact that these creatures had accom- plished their nefarious work before discovery, suggested to my mind the most dangerous side of the circumstance, for forewarned is forearmed. I wish particularly to note this fact, and hope that it

may reach the recognition of some of those who may be similarly placed. This was not all the harm. Wherever there was a mark of the leech showing its attachment, an ulcer resulted in over 75 per cent. of the cases. These, apparently at first harmless sores, soon developed into the characteristic tropical ulcer, with all its tardiness in healing, and other unfortunate consequences. These ulcers ultimately were a cause of great suffering, adding to the exhaustion from loss of blood in the primary stage.

It is true, moreover, that insects not only expend their poisons with their stings—there is another easy avenue. In the vile habit of "tuba" drinking, there is presented a favorable means of spreading toxins by the wholesale, and in concentrated form. Some little explanation here is not amiss. "Tuba" is an intoxicating liquid made by the Filipinos, who cut off the blossom stalk of the cocoanut tree, and then collect the escaping sap from the stump so left into a bambo tube (about three feet in length and five inches in diameter), hence the name "tuba"; it is then fermented with a native bark, strained, and is ready for use. This tube is fastened in the tops of the tree, allowed to remain there maybe for days before it is filled, and then another tube takes its place. In the meantime, every sort of insect gets at it, "tuba" having an attraction for bugs; they swarm about the fermenting liquid, fall in, and die. Although the natives may strain out dead insects after removing the tube from the tree, there remains in liquid form a strong essence of bug. This, to my mind, is the main reason why the drink is so poisonous, and consequently is considered by local authorities to have on the troops a decided maniacal and deadly influence. Not only do insects haunt the tuba trees (so called because such trees bear no fruit, and are used for the manufacture of tuba exclusively), but small birds and even bats have acquired the habit, and they, too, sometimes fall in. I know a case in which an enormous fruit bat got so drunk on tuba that it first became quarrelsome with its neighbors, and then dropped down out of the tree upon the ground in a semi-paralyzed state. The concoction known as bino is another alcoholic poison that I would warn the American (living in the Philippines) against. This bino is a vulgarism for the Spanish vino, and is made of anything the most handy. When anyone asks for bino he may get a poor red wine or a bad white wine, doctored to suit the market; and when the natives are so disposed they will put in red pepper, or wood alcohol, because it then savors more of alcoholic stimulant, whatever else it contains is guesswork, but in most cases it contains this methyl alcohol. It may be safely said that alcohol is not a necessity, as some have advanced, in any part of the tropics; but if one is addicted to the use of it, he should confine himself to the best that is to be had, and he should never indulge in the drug until his system has awakened for the day's work—that is to say, he should never drink before the midday meal. My sincere opinion is, that it is better not to drink any while serving in the Philippines, unless prescribed by a competent physician, and even then many stimulants are at hand which are equally as good. To live properly, dieting oneself and keeping down deposits of uric acid with plain food, is far better than to overstimulate the system, thus fooling ourselves into believing that we are capable of as much work in the tropics as elsewhere. It is impossible to exert the energies of white men more than that which the natives themselves attempt. Therefore it should be a rest of the body during the heat of the day, no work between the hours of eleven in the forenoon and three in the afternoon; most of this time must be employed in rest, or, better, sleep. One should avoid the sun as much as his duties will allow, and when obliged to be in it, a perfect protecting head covering is imperative. Do not expose the head or face to direct sun rays, and keep your eyes well shaded. I have seen the eyes so sunburnt as to permanently weaken them. A thick cork or pith helmet, large and drooping in the rear, to protect the nape of the neck, is the best head-gear. Do not weaken the mucous membranes with alcohol or stimulating food, such as curried meats, and protect the skin as much as possible, ever on the alert to help nature in protecting those tissues which must bear the brunt of climatic conditions. A mild solution of tepid carbolic acid (¼ per cent. phenol in water) sponged over the body after the daily bath will do much to prevent skin diseases, and is far better than stronger solutions applied after the trouble has set in. My suggestions as to the mode of life in the Philippines are: To avoid over stimulating, avoid the sun, and keep the body cool by frequent bathing. If it can be afforded, cool your residence with one of the numerous refrigerating stoves on the market. Lemon or lime juice in water is much more wholesome than alcohol. For we look carefully into the many fancy-named fevers we find that the congested liver is responsible in a likely number, and therefore calomel and soda are more called for than the antipyretics. My own experience allows me to make this assertion. When the tissues become lax, as is observed in many cases of dilatation of the stomach and dropsical effusion into the lower limbs, then it is time to take two or three months vacation and go to a colder clime. Disillusion yourself of the notion that alcohol as stimulant will rejuvenate these enervated tissues and beware of the advice of such charlatans as would influence you into postponing your vacation at this critical period by advising alcoholics. When these symptoms of laxity and depletion appear, I repeat that it is time to leave the Philippines, remaining away until there is a resilience back to the normal of the weakened condition. In conclusion I may add a few short hints as to daily life *apropos* of my personal observations above stated. The wearing of a flannel band about the abdomen is not a necessity, but a habit and notion handed down by the British pioneers of India. I am convinced, however, that the abdomen should be protected while sleeping; at other times the everyday wearing apparel and exercise supply enough heat to prevent the chilling by evaporation of sweat. I would advise, whenever it is necessary to lie down and sleep, that a blanket be handy to throw over the abdomen, and in some cases of very restless sleeping a broad flannel band may be substituted at bed time. Water supply is the one thing where care is imperative; drink distilled water if possible, and have your clothing washed in the same; if the latter cannot be done, the wash clothes must be boiled. I believe, if the Secretary would establish a regular rate, designated laundryman, and if each ship was allowed its quota. thereby having the ship's washing done on board (with distilled water) it would materially prevent the spread of the many mild forms of so-called dhobi (or dobie) itch sometimes found in the navy. I would strenuously advise that food handled by natives to any great extent be debarred from the messes, not that I wish to criticise the Filipino's personal habits, but my observation prompts me very clearly in this matter and I sincerely believe I am correct in warning against it. The natives, as a rule, do not keep their hands clean, although it is said their bodies are

ushed daily; nevertheless they are not microscopically clean. I would advise Americans to be extremely careful of this little detail, as it may seem, and I would moreover advise the laity to accustom themselves to the art of disinfecting their own hands by occasional ablutions in one-tenth per cent. solution of bichloride of mercury. They should be cautioned to use the hands for what they were created, and be warned against such acts as scratching; use a disinfected wood or ivory "back-scratcher" (a common utensil in the far East), and only when imperative. Keep the hands away from your face and hair as much as possible during working hours. Scrupulous care of the teeth is another precautionary measure against disease in the tropics; by this I may include perfect cleanliness of the mouth, nose, and fauces. My plan is to clean the teeth upon rising and upon going to bed with a camphorated saponaceous dentifrice, not using enough force to injure the enamel; after this, rinse the mouth and gargle the throat with warm Dobell's solution of boric carbolic mixture. It is advisable and as well at these times to snuff some of the warm antiseptic fluid up the nostrils, allowing it to flow past the posterior nares without swallowing; with a little practice this can readily be done without causing gagging or flooding the eustachian tubes. Adopting these habits of microscopical cleanliness, I am convinced that the chances for contracting contagion are reduced to a minimum. There were many other topics bearing on the train of thought expressed in this paper, but those only striking me the most forcibly I submit now, trusting that some good may possibly be gained from these few personal impressions and observations. In conclusion I wish to say that Americans are now beginning to learn how to live in the Philippines, and I am pleased to observe this. I would suggest that my plan of cooling dwellings by the various new methods of refrigerating stoves be tried, if only as an experiment.

PORTSMOUTH, VA.

VALUE OF TOTAL AND DIFFERENTIAL LEUCOCYTE COUNTS DURING THE COURSE OF TYPHOID FEVER.

BY HENRY A. HIGLEY, M.D.,
BROOKLYN, N. Y.

ALTHOUGH from the viewpoint of diagnosis the total and differential leucocyte counts of typhoid fever have received due consideration, but little has been written relative to the knowledge which is to be obtained by these means during the course of the disease. This is the more surprising since the characteristics of these counts in the middle and latter weeks of typhoid fever are well known and established beyond all question. Such characteristics are a reduction in the total number of leucocytes combined with a relative increase of the large mononuclears, and a relative decrease of the polymorphonuclear neutrophilics. It might, therefore, be supposed that frequent leucocyte counts during typhoid fever would be of value in enabling the clinician to thoroughly keep in touch with the protean clinical picture of the disease. That in reality such is the case there can be no question. The following examples are submitted in support of this assertion:

CASE I.—C. P., age twenty-four years. This patient showed the ordinary clinical course of typhoid fever up to the latter part of the third week. In the latter part of the first week the total leucocyte count was 8,000, and the differential count at that time showed large mononuclears, 19.4 per cent.; polymorphonuclear neutrophilics, 67.8 per cent. On the twelfth day the Widal reaction was first tried and found positive (1–50). On the fourteenth day the total leucocyte count was 6,500, and the differential count gave large mononuclears, 22.5 per cent.; polymorphonuclear neutrophilics, 61.2 per cent. Counts on the nineteenth day gave the following results: total count; 10,500, differential count, large mononuclears, 10.2 per cent.; polymorphonuclear neutrophilics, 78.6 per cent. Up to and at this time the clinical picture of the disease showed absolutely no deviation from the usual. On this day the temperature was pursuing the usual course, and a most careful clinical examination failed to reveal any cause for the alteration in the characteristics of the total and differential counts. Nevertheless, the case was regarded with suspicion. On the following day (the twentieth) the clinical picture was still undisturbed, but the total leucocyte count was 12,000—the large mononuclears showing 8.9 per cent., and the polymorphonuclear neutrophilics, 84.6 per cent. These counts were made on the evening of this day. The next morning (the twenty-first day) the patient was seized with a severe chill, followed by accelerated respirations and a sudden rise of temperature to 105.6° F. A physical examination of the chest showed a beginning consolidation of the right lower lobe. The total leucocyte count was now 19,000—the large mononuclears, 6.2 per cent.; the polymorphonuclear neutrophilics, 89.4 per cent. A microscopical examination of the sputum showed that it was loaded with a capsulated diplococcus, as stained by Welch's method. The patient died from the complicating pneumonia on the twenty-fourth day.

CASE II.—D. .P., age seven years. This was a case of typhoid fever, which was complicated by measles in the first part of the second week. Typhoid bacilli had been isolated from the fæces by the Hiss method on the sixth day. The Widal reaction was negative on the fifth, but positive on the eighth day in a 1–50 dilution. On the fifth day the total leucocyte count was 6,750, the percentage of large mononuclears being 25.1, and that of the polymorphonuclear neutrophilics 54.6. On the ninth day a severe bronchitis with coryza developed, the rest of the clinical picture remaining the same. The total count on this day was 4,500, but polymorphonuclear neutrophilics were present in 86.1 per cent., the large mononuclears showing 3.2 per cent. Confirmatory counts on the tenth day gave practically the same figures. The bronchitis and coryza increased in severity, and on the thirteenth day an abundant eruption of measles appeared. Simultaneously there was a marked fall in the temperature (no antipyretic measures having been used) from 104.2° F. to 101.3° F. The characteristics of the total and differential counts were found to be the same as on the ninth and tenth days. The eruption of measles remained for five days, during which time the case was a typical one of measles, with a low temperature—this never going above 101.3° F. With the fading of the measles eruption on the eighteenth day, the total leucocyte count was found to be 4,150—the large mononuclears showing 21.8 per cent., and the polymorphonuclear neutrophilics 59.3 per cent. On the evening of the eighteenth day the temperature was 104.1°F. From this time on the case ran a typical course of typhoid fever—the total and differential leucocyte counts also remaining typical. Recovery ensued after an eight weeks' course dating from the time of the beginning of the typhoid fever.

CASE III.—A. H., age eighteen years. This was a case of typhoid fever marked by two relapses. The first attack ran a nine weeks' course and showed an atypical temperature throughout. The Widal reaction was positive (1–50) on what was probably

the sixth day. On this day the total count was 8,000—the polymorphonuclear neutrophilics showing 64.8 per cent., and the large mononuclears 18.4 per cent. On the sixty-third day the temperature first reached normal. For four days thereafter it remained practically normal. On the sixty-eighth day it began to rise. By the seventy-second day it had reached an evening height of 103.2° F. The question now arose as to whether this was a relapse or a new infection of other than typhoid origin. On this day the total count was 4,000—the percentage of polymorphonuclear neutrophilics being 48.1, and that of the large mononuclears 32.9. On the basis of these counts the opinion was given that the existing temperature was due to a relapse of the typhoid fever. Subsequent events confirmed this opinion—the relapse running a ten-days' course, to be followed by a similar relapse and final termination in recovery.

Conclusions.—These cases show that so long as the typhoid infection remains pure the characteristics of the total and differential leucocyte counts peculiar to this disease are maintained.

In the presence of complicating infections these characteristics are altered. Such an alteration precedes the clinical picture of the complication. Therefore frequent and careful total and differential leucocyte counts during the course of typhoid fever are of great value in enabling the clinician to keep in touch with the variations in any given case.

In conclusion, I desire to express my thanks to Dr. Herbert F. Williams, whom I am indebted for the opportunity of observation in one of the above cases.

227 PARK PLACE.

A NEW SIGN OF BASILAR MENINGITIS.

BY G. W. SQUIRES, M.D.,
EAST AVON, N. Y.

To discover a new sign is, to tell the truth, more often the simple act of putting it in print. Many a modest practitioner knows clues to the recognition of disease that he never thinks of putting on record, and the world keeps on searching for the knowledge that perished with him. Among diseases of childhood the insidious attack of tuberculous meningitis is avowedly difficult of diagnosis. When the historic symptoms of the disease, headache, vomiting, drowsiness, constipation, and perhaps convulsions declare themselves, the physician would very probably be directed to an apprehension of some meningeal trouble when reflex symptoms and pupillary signs are fully developed with retraction of the head and the Kernig sign, the case can with much confidence be diagnosed basilar meningitis of tuberculous origin. A sign which I have invariably found to be present in this disease, frequently so early as the fourth or fifth day, according to the severity of attack, is a rhythmical dilatation and contraction of the pupil. The method of obtaining the sign is as follows: Place the child's head between the knees of the physician face upward, with the body of the child supported on the bed, table, or lap of the nurse. Grasp the sides of the child's head with each hand and produce gradual and forcible extension of the head on spinal column. As the head is brought back in this extension the pupils will be seen to commence to dilate simultaneously with the commencement of extension the more extreme the extension the more the dilatation. Now upon flexion the pupils contract so that when the chin is forcibly brought to the manubrium the pupils are well closed up. This can be done several times a minute, and each time the pupillary phenomenon will be repeated. The dilated pupils, with extreme retraction of the head in the late stages of the disease, may be in some measure mechanical or hydrostatic from increased pressure by effusion on the nerve roots or centers at the base of the brain. An early recognition and treatment of this disease is very important if we would hope to save many of our little patients.

The Influence of Skin-grafting on the Recurrence of Morbid Growths.—The influence of skin-grafting on the recurrence of morbid growths is a subject of great interest. Dr. Robert Campbell, writing to the *British Medical Journal* of February 13, refers to this matter as follows: "I have found in cases of lupus that if the affected skin be excised and skin-grafting of the raw surface be employed there is no tendency for the disease to recur; whereas, if the wound be stitched up, there is a marked tendency to the formation of tuberculous nodules in the stitch holes and scar. The same observation applies to keloid scars. I have also reason to believe that skin-grafting exercises an inhibitory influence on the recurrence of sarcomata of the skin. I have not yet been able to satisfy myself that carcinomata are affected in the same way. I think the question is one which is worthy of investigation."

Diagnosis of Incipient Consumption and the Cases Suitable for Sanatoria.—C. H. Cattle would admit to the sanatorium all patients having the disease limited to one lung without clinical signs of cavity and having a temperature very little above normal after the patient has been put to bed for a week or two. He believes in putting all patients to bed as a preliminary for treatment. He thinks that cases of pleurisy should have a three months' course in the sanatorium after the active symptoms have subsided. Most pleurisies are tuberculous and the disease is probably latent in the lung at the same time. These cases probably furnish the examples of healed tuberculosis. When there is evidence of constitutional disturbance, as when latent lesion is about to become evident on physical examination, sanatorium treatment should be adopted. Acute cases are not suitable for treatment away from home until the acute symptoms disappear without much destruction of lung tissue, except in selected cases in middle life, when the disease has a tendency to spontaneous cure. Cases with glycosuria, tubercle of the kidney, ulceration of the intestines, or other grave complication are not suitable for the sanatorium intended for permanent cure. Phthisical patients should not be sent to the sanatorium without due consideration of the possibility of relapse.—*The Practitioner.*

Chronic Synovitis Due to the Organism of Mediterranean Fever.—J. P. Kennedy reports the case of a patient who suffered from what was called subacute rheumatism of the shoulder contracted after a wetting. At first he had persistent pains in the various joints, which finally settled in the right shoulder, which became swollen. No treatment had much effect. Hot fomentations gave the most relief. The shoulder was much swollen, tender, and tense; the deltoid was wasted with fluctuation on both sides of it. Diagnosis was that of a large subacromial bursitis. The blood was negative for Widal's reaction to Mediterranean fever. Fluid from the bursa showed small cocci. The joint was much relieved by drawing off the small amount of fluid, and the evening temperature fell from 100° to normal. Injection of one to eighty carbolic-acid solution 20 minims, produced a rapid recovery. The organism was proved by inoculation to be Micrococcus melitensis. The writer thinks that the reason he did not get a reaction for Mediterranean fever by Widal's test was because the dilution used was too high (1-40 and 1-100 respectively). It should not be diluted over 1 to 30. He also thinks that the seven local symptoms found in this fever are due to deposits of the micrococcus in the affected tissues. Often an external exciting cause can be found for these local affections, which are very frequently located in the shoulder.—*Journal of the Royal Army Medical Corps.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, March 26, 1904.

MEANS OF DIMINISHING SMALLPOX.

The *Hospital* of February 13, 1904, contains an article by J. E. R. Stephens, Barrister-at-law, dealing with the recent report of the British Royal Commission on vaccination. The work of the commission has been very thorough, and, of course, the conclusions reached are instructive in the highest degree. The report stated in part: "We can see nothing to warrant the conclusion that in this country vaccination might safely be abandoned and replaced by a system of isolation. If such a change were made in our method of dealing with smallpox, and that which had been subsituted for vaccination proved ineffectual to prevent the spread of the disease, it is impossible to contemplate the consequences without dismay. Power would, in our opinion, be conferred on sanitary authorities to give compensation for loss of wages, and generally pay expenses occasioned either by the isolation of patients, or persons who have come into contact with them, or such supervision of them as is necessary, whether in hospital or elsewhere." The commissioners paid special attention to the fact that the common lodging-house is frequently the "*fons et origo*" of smallpox, whence the malady does spread far and wide. Tramps who wander throughout the country contract the disease, and carry it from place to place. The following recommendations were made in view of this theory:

(1) That common shelters which are not now subject to the law relating to common lodging-houses should be made subject to such law.

(2) That there should be power given to the local authority to require medical examination of all persons entering common lodging-houses and casual wards to see if they are suffering from smallpox, and to offer a reward for prompt information of the presence of the disease. (3) That the local authority should have power to order the keeper of a common lodging-house in which there has been smallpox to refuse fresh admissions for such time as may be required by the authority. (4) That the local authority should be empowered to require the temporary closing of any common lodging-house in which smallpox has occurred. (5) That the local authority should have power to offer for lodgings to any inmate of a common lodging-house or casual ward who may be reasonably suspected of being liable to convey smallpox. (6) That the sanitary authority should give notice to all adjoining sanitary authorities of the occurrence of smallpox in common lodging-houses or casual wards. (7) That where the disease occurs, the public vaccinator, or the medical officer of health, should attend and vaccinate the inmates of such lodging-house or wards, except such as should be unwilling to submit themselves to the operation. One of the questions put to the commission was as to the objections made to vaccination on the ground of injurious effects alleged to result therefrom, and the nature and extent of any injurious effects which do, in fact, result.

The majority of the commissioners, in answer to this query, considered, in the first instance, the evidence afforded by infantile mortality, vaccination being in most cases coincident in point of age with infancy. "If then," said the commissioners, "it is the parent of other diseases, and has substantially augmented the number of deaths due to them, we should expect to see some effect produced on infant mortality as a whole; yet it is clear that the majority of infants in the first year of life, as measured by the proportion of their deaths to births, has not increased at all during the times when infant vaccination has been increasing."

Referring to syphilis as a result of vaccination, the report says, "If vaccination were, to any serious extent, a cause of syphilis we should have expected to see some evidence of it in the comparative records of the mortality of infants under one year of age. Statistics disprove this allegation.

So far as cancer is concerned, the commissioners deliver themselves of this view of the situation: "It may be that, in addition to the apparent increase, there has been some real increase in the mortality from cancer; but there is not a shadow of evidence to connect this with the practice of vaccination, whilst there is strong evidence pointing the other way."

As regards the connection between erysipelas and vaccination the commissioners remark as follows: "The evidence, is, in our opinion conclusive to show that there has not been, during the past forty years, any material increase of deaths from erysipelas owing to vaccination."

The report further stated: "An examination of the analysis of the fatal maladies connected with vaccination during the period 1886 to 1891 made by Dr. Ogle, shows that erysipelas is credited with almost one-half of the total number of deaths. Next in number comes the class which includes pyæmia, septicæmia, and blood-poisoning. If this class be added to erysipelas and maladies allied to it, they account altogether for two-thirds of the cases in which the cause of death has been connected with vaccination."

Commenting upon Dr. Ogle's statement, the commissioners said: "It is not always easy to determine whether vaccination has been the cause of or has contributed to subsequent erysipelas or blood-poisoning. Erysipelas is a common disease of infancy, and not infrequently leads to death. The evidence of Dr. Ogle shows that nearly two thousand per million die of erysipelas during first three months of life, and that the mortality rapidly declines as the age advances. Quite apart then from vaccination, there is nothing remarkable in the occurrence of erysipelas in the case of an infant. The disease is obviously contracted, in the majority of cases, from some other source."

A careful examination of the facts which have been brought under the notice of the commissioners enabled them to arrive at the conclusion that, although some of the dangers said to attend vaccina-

tion are undoubtedly real, and not inconsiderable in gross amount, yet, when considered in relation to the extent of vaccination done they are insignificant. There is further reason to believe that they are diminishing under the better precautions of the present day, and with the addition of the further precautions which experience suggests they will be less and less in the future.

That part of the report which refers to the spread of smallpox by tramps and common lodging-houses would seem to be even more applicable to this country than to Great Britain. Tramps abound here, and they are always more or less moving from place to place. Smallpox has been particularly prevalent in the United States during the past four years, and it is extremely probable that tramps have been largely instrumental in disseminating the disease. The matter is worthy of investigation, and if it be found that smallpox is spread by these means, precautionary measures should be taken at once.

THE ROCKY MOUNTAIN "SPOTTED" OR "TICK" FEVER.

Recognized by Montana physicians for fifteen or twenty years as a distinct clinical entity, but hardly noticed in the literature, this disease is somewhat exhaustively discussed by Drs. Louis B. Wilson and William B. Chowning in the *Journal of Infectious Diseases*. The authors propose for it the name *Pyroplasmosis hominis*. The center of the disease seems to be the Bitter Root Valley, Montana, though cases have been reported from Idaho, Nevada, and Wyoming. Of 126 cases, 105 occurred in April, May, and June, with the maximum time limits as March 17 and July 20. Men furnished 79 of the 126 cases, probably from their increased exposure to contagion in roaming the foothills, which is the principal infected area. Most physicians experienced in the disease recognize but one type, the "spotted" one, which is severe, and is fatal in 70 to 80 per cent. Accurate diagnosis of the mild type offers much difficulty. Though its existence must be admitted, during the author's investigations all cases but one were of the severe form, the diagnostic feature of which is the "spots." The disease in Idaho appears to be much milder, though all cases show the characteristic eruption. Where elicited, the incubation period was two to eight days. The onset is of the type usual in general infections. The initial chill is usually the most severe, the recurrences decreasing in severity. At the outset there is severe aching in the bones and muscles, usually great weakness, and there may be severe headache. Constipation is usual, bronchial cough is frequent, and there is considerable restlessness. The urine is usually scanty, and high colored, and sometimes albuminous. The skin is dry and the tongue heavily coated (first white, later brownish), and finally it becomes dry and cracked. Sordes appear early and may be quite pronounced. The whole facies is thus very like typhoid fever. The fever on the second day may be 103 or 104, and increases to a maximum of 105–107 on the fifth to the seventh day. Recovery is usually by lysis, the fever diminishing about the end of the second week to normal two to four weeks later. The eruption appears two to five days (in sixty-five cases on the third; in two on the ninth) after the chill, first about the wris and ankles or the back, thence extending over th body, usually last on to the abdomen, generall taking two days to reach the maximum. Th scalp, palms, and soles are frequently covered The eruption is circular, rose-colored, and macula the color at first disappearing on pressure. Rapidly however, the character changes, the macules be coming permanent, dark blue or purple, and con fluent, imparting a mottled appearance. Som jaundice is generally present. About the thir week desquamation (usually slight) begins. Som severe cases show low muttering delirium, and pick ing at the mouth, ears, and bedclothes may b present. Except at the outset, the disease is re markably free from pain. The rapidity of th pulse, and sometimes also of the respiration, ma be out of all proporton to the temperature. Th blood count shows a marked reduction in the re cells and hæmoglobin, with at times a slight leuco cyte increase. Freshly drawn blood shows sparing inclusions in the red cells of organisms showing th characters of *pyroplasma*. The spleen is uniformly enlarged and tender. All severe cases show mor or less œdema of the face and extremities. Naus and vomiting develop about the beginning of th second week and in fatal cases continue to the end Some cases show nausea from the onset. Nine cas examined showed granular and blood casts. Res ration is usually not over 36, but sometimes reaches 60. It is regular, but usually shallow.

The macroscopic lesions post mortem are: Earl and intense rigor mortis; skin marbled or petechia in all cases tick bites; hypostatic congestion o lungs; myocardium soft, the right ventricle fille with dark fluid blood, the left almost empty or with only a small clot; spleen 3–3½ times the norma weight, dark red, soft, and almost diffluent, outlin of the Malpighian bodies almost obliterated; liv slightly enlarged and pale; kidneys with sma subcapsular hemorrhages and congested corte Microscopically the skin shows changes referabl to interference with the capillary circulation, th extravasation and pigmentation accounting fo the persistence of the "spots" long after recovery The heart muscle, spleen, liver, and kidneys, show parenchymatous degeneration.

From the standpoint of etiology, the disease i strictly limited to the west side of the Bitter Roo Valley; it is confined to one season (March to July) there is not even a suspicion of direct transference from one person to another, and the avenue of in fection seems clearly to be the tick bite. The main reasons for implicating ticks as carriers of the in fection are that in all the cases tick bites preceded the onset, and that no other carrier was suggested by the study. Ticks appear about February 15 and disappear about July 15; the sharp geographical limitation by the river harmonizes with the transmission by a temporarily parasitic animal of slow locomotive powers; one case was definitely known to have been induced by a tick bite; and lastly ticks play the rôle of transmitters of the nearest known relatives of the parasite, *e.g.* of *Pyrosom bigeminum*, the causative organism of "Texas fever" of cattle. No bacteria of etiological importanc were found.

There is some reason to incriminate one of th

rodents of the region, *Spermophilus columbianus*, a third host of the parasite, though such a multiplicity of hosts has not yet been recognized for the hæmocytozoa. Still no parasites were found in the blood of other animals, or in that of over one hundred persons unaffected by "spotted fever;" parasites indistinguishable from the pyroplasmata were found in the blood cells in ten out of fifty-one spermophiles from the west side of Bitter Root Valley, but in none of those of sixty-two from the east side of the same valley; *Spermophilus columbianus* is very abundant on the west side, much less so on the east side of the Valley; it is averse to swimming; and during spring the Bitter Root is swollen to a torrent, and *Spermophilus columbianus* is out from hibernation only from about March to August 1, and ticks were found upon them; and finally experiments showed that the pyroplasmata could live a long time in the blood of another rodent (rabbit) without causing symptoms.

Early diagnosis is sometimes extremely difficult or impossible. When, however, in spring or early summer in the infected area, constipation, headache, pain in the back or limbs or radiating from the tick bite, muscular soreness, chill followed by fever and usually mental apathy occur, pyroplasmosis is to be suspected; and the diagnosis becomes positive when the rash appears (usually on the third day and first on the extremities), or when pyroplasmata are found in the blood.

Treatment would appear to be eminently unsatisfactory. Quinine in large and small doses has been tried, but the results seem hardly encouraging.

EPIDEMIC DYSENTERY.

During the past half-dozen years much discussion has arisen relative to the specific bacterial etiology of epidemic dysentery. Unfortunately not a small portion of what has been written upon this subject concerns claims of priority in the discovery of the causative bacillus as advanced by different observers. In such discussions the medical profession have little or no interest, and it is also evident that their continuance conduces in no great measure to our knowledge of the causation of this disease. It is, however, interesting at the present time to note that out of this chaos of opinions and diversity of claims the true status of affairs is formulating, so that even now it is possible to forecast with much certainty what will ere long be recognized as indisputable truth. The protean clinical picture of epidemic dysentery has been acknowledged for many years. Within this disease have been included cases which range all the way from the acute dysentery of camps through the various degrees of ileocolitis to the infective diarrhœas of infants and adults. It is somewhat surprising that for classes of cases which show such clinical diversity a bacterial entity should have been considered possible. When the symptomatology is taken into consideration there does not appear to be any definite reason why an epidemic in Japan and another in the United States or Germany should be regarded as necessarily caused by the same microorganism. As a matter of fact, there have been a number of varieties of so-called dysentery bacilli isolated in different epidemics from the stools of patients suffering with epidemic dysentery. These varieties differ to a certain extent in cultural peculiarities and also in their pathogenic properties when inoculated into animals. R. H. Firth (*Journal of the Royal Army Medical Corps*, December, 1903) has made a special study of the cultural and pathogenic characteristics of many of these varieties. He comes to the conclusion that certain of these species are practically identical—as, for instance, those isolated by Shiga, Kruse, Vaillard, Harris, and Flexner, Nos. 1 and 3. Others are easily to be differentiated from these. There does not seem to be any question but that all of the varieties are distinct from the bacillus coli communis and the typhoid bacillus.

Firth's work shows a careful technique and adds evidence to opinions which have been expressed in other quarters. There are probably a number of varieties of bacilli capable of giving rise to the clinical picture commonly regarded as epidemic dysentery. These bacilli certainly belong to a group of closely related microorganisms. Whether or not they are interchangeable forms cannot now be definitely stated, but it is very improbable that such is the case. Under these cricumstances the important practical point is that an immunity to one of these varieties does not imply an immunity to the others. The difficulties of an effective serum therapy are therefore apparent.

The Selection of Cases of Pulmonary Tuberculosis for Treatment in Sanatoria.

With increasing hopefulness in the treatment of pulmonary tuberculosis has grown a demand for early diagnosis, as the results will be the better the earlier treatment is instituted. To await the development of distinct physical signs or the appearance of tubercle-bacilli in the sputum is to lose valuable time and with it therapeutic opportunity. The problem presented is in large measure a physiological one, and comprises a fortification of those natural resisting influences through which the invasion of the causative microorganism is ordinarily repulsed, or its effects are neutralized when it succeeds in obtaining lodgment in the tissues. Of the means for attaining this end, first place must be given to an abundance of pure air and sunshine, while the question of food is scarcely of lesser importance. Whatever tends to the improvement of the general nutrition must be considered as an adjuvant in the treatment of pulmonary tuberculosis. It has been found that the necessary measures can be best applied in institutions favorably situated, adequately equipped and intelligently administered, but some discrimination is required in the selection of cases, in order that the best results may be obtained, and the methods do not fall into disrepute. In a paper dealing with this subject, Dr. C. H. Cattle (*Practitioner*, February, 1904) gives expression to the view that patients in whom the disease is limited to one lobe of a lung, without clinical signs of a cavity, and the temperature does not range much above the normal after rest in bed for a week or two, may be received into a model sanatorium. Many cases of pleurisy, it is thought would be better for a three-months' course at a sanatorium after subsidence of the active symptoms. A considerable proportion of such cases are tuberculous, the disease being latent in the lung at the same time. When from the presence of constitutional disturbance a latent lesion gives indication of becoming evident to physical examination, sana-

torium-treatment should be adopted. Dr. Cattle believes that acute cases are not suitable for treatment away from home unless the acute symptoms subside without great destruction of lung-tissue. Cases that exhibit early a tendency to cavity-formation are considered ineligible for sanatoria, which aim at cure within a limited period, and cases should be debarred in which a cavity can be recognized, except under special circumstances, as, for example, when the disease is chronic and there is no tendency to hemorrhage and there is evidence of considerable repair. In persons who are getting on toward middle age the disease often manifests a tendency toward spontaneous arrest; hence, a greater extent of disease may in their case be consistent with the hope of ultimate recovery than in the majority of younger persons. Also cases of glycosuria, of tuberculosis of the kidney, of intestinal ulceration or other grave complication are considered unsuitable for treatment at a sanatorium that aims at permanent improvement or cure. For various reasons a considerable proportion of cases relapse and gradually lose the good that had been gained. This fact should be taken into consideration in sending poor patients to sanatoria, and it also raises the whole question of the after-care tuberculous individuals.

The Volume of the Red Cells in Various Diseases.

The *Journal of Medical Research* for December, 1903, contains a "Study of Volume Index," by Dr. J. A. Capps. By "volume index" is meant the quotient obtained by dividing the volume percentage of the corpuscles as obtained by the hæmatocrit by the percentage of the normal number of cells shown by the blood count, this quotient representing, in the author's opinion, the only reliable test of the volume of the red cell relatively to the normal. Measurement of diameters is of limited value and is often misleading. Especially is the use of saline admixtures to prevent coagulation a procedure to be avoided, as in order that the solution may be in osmotic equilibrium with the blood, a special test would have to be made with each blood. The best results Capps finds to follow the use of blood alone. Two precautions are vital to avoid coagulation, namely: scrupulous cleanliness of the tubes, and speed, the blood being put, within a few seconds after it is drawn, into the hæmatocrit, which should then be revolved at a uniform speed of 10,000 revolutions a minute, for three minutes. Operating thus, Capps finds the cell volume invariably increased in pernicious anæmia and usually more so than the hæmoglobin content. The heightened volume index is a more constant and trustworthy sign than the increased color index. The polychromemia is due to increased cell volume and not to increased affinity for hæmoglobin. Moderate cases of secondary anæmia show only a slight loss in volume, but in high-grade anæmia the cells become small and atrophic. A small group of secondary anæmias exhibit during the early stages the low color and volume indices of chloranemia; later on as oligocythemia becomes marked, macrocytism, with high color and volume values, resembling pernicious anæmia, occurs. In a large proportion of chlorotics the cell volume suffers as well as the hæmoglobin content, though always to a less extent. Prognostically, the condition of the volume index is important. A normal, or nearly normal, volume index indicates a quick recovery, even though hæmoglobin is much reduced; but a low volume index entails a slow response to treatment and tedious convalescence. That is, the cell must grow to normal size, before it can take up its normal amou of hæmoglobin. Color loss is always greater a takes place more rapidly than loss in volume, wh during recovery volume is restored before color rea es normal. Normal hæmoglobin content repres protoplasmic saturation, wherefore color indi above normal necessitate an assumption of increa volume, supersaturation with hæmoglobin probab never occurring. Volume seems to be chiefly alte by influences affecting cell growth or degenerati The large erythrocytes of pernicious anæmia probably young cells. Small cells may result fr malnutrition of the bone marrow (chlorosis), actual degeneration (sepsis). Cell volume suff remarkably little change from osmotic influen An explanation of this lies in the fact that molecular density of bile and lymph present in ja dice and dropsy is nearly the same as that of bl serum. Osmosis cannot be responsible for the alterations in chlorosis, as their shrinkage in volu is accompanied by great loss of hæmoglobin. increased osmosis cannot be the cause of increa cell volume in pernicious anæmia, as there the ce rich in hæmoglobin. Capps has never observed "acute swellings" described in dropsy, hemorrha and jaundice.

Cancer in Australia.

Theories as to the causation of cancer, while noting the extreme interest taken in the mat are at the same time somewhat confusing. origin of the disease is sometimes attributed causes which seem to the ordinary medical m vague and improbable. Nevertheless, it is well t the question should be discussed from every p of view, for it has not infrequently happened t great scientific discoveries have owed their solut to apparently most unexpected agencies. Writ in the *Lancet*, February 20, concerning cancer Australia, Dr. G. Cooke Adams propounds a theory with regard to the origin of cancer on t continent. The writer summarizes his views as lows: (1) That cancer is not due to a bacteria parasitic origin; (2) that cancer is a constitutio disease due to a specific or malignant virus origina in the blood and chiefly manifesting itself after thi five years of age, and at its greatest virulence tween fifty and seventy years of age; (3) that ma nant disease may be congenital, and certain fo acquired by infection or contagion; (4) that principal factor in the cause is hereditary tende (5) that the principal exciting factor is prolon local irritation acting on a constitution suffering f an inherited tendency or which has been debilita through want of treatment of one or other of following diseases in their order of frequen syphilis, alcoholism, obesity, rheumatism, gout tuberculous disease; (6) that the principal diet factors in the cause are sugar, beer, and alcol (7) that the principal hygienic factors in the ca are woods and forests whose dropping foliage, composing, causes stagnation of water; also ba formed streets and defective drainage in cities, the overcrowded badly housed and fed populatio cities; (8) that cancer is preventable disease, and t the absolute cure is only to be found in the means preventing its exciting causes and completely moving the same; (9) that the sanitary indigen foliage of the following natural orders—(*a*) myrtac (*b*) lauraceæ, and (*c*) coniferæ—appears to exert specific influence in rendering the native born popu lation of the countries where they grow almost im mune from malignant diseases other than might b caused by prolonged local irritation (the Australia eucalypts belonging to the myrtaceæ exert the great

st influence in this direction) possesses a specific ction in arresting the pathological progress and rocess of malignant diseases, and (10) that all in- rnal and local treatment should be absolutely voided, more particularly such local treatment as he *x*-rays and Finsen's light, as they are likely to st up secondary conditions around the site of lesion. ar better is early and prompt removal when the alignant growth is accessible.

Dr. Adams' opinions respecting cancer are novel nd not in accordance with the result of the re- arches of recent investigators. The fact, however, distinctly curious that native-born Australians ould not be susceptible to cancer only to a small tent. There are few who will agree with the writer to the non-effectiveness of local treatment. The stimony regarding the beneficial influence of *x*-rays nd Finsen's light is too strong to be disregarded. hat internal treatment is of little use is doubtless e opinion of the majority of the medical profession ho have had experience of cancer, while the em- oyment of radical measures is always indicated hen the malignant growths are accessible.

The Divorce of Pathology from Medicine.

The Senatus of Edinburgh University is said to e engaged at the present time in the rearrangement f the whole medical curriculum. Mr. Stuart Mac- nald thinks, therefore, that it is a good oppor- nity to put forward a plea for different methods the teaching of pathology, and expresses his ews on the subject in the *Scottish Medical and rgical Journal*, February. The writer is of the inion that the modern relation of pathology to edicine receives too scant attention, and argues that reëminence in medicine without a thorough ground- g in pathology is hardly possible. In view of the bove facts, he considers that this modern divorce f pathology from medicine can only be regarded ith alarm.

Mr. Macdonald points out that recent appoint- ents to chairs of pathology in Great Britain has een filled by men who have devoted themselves ntirely to pathology, and who have taken a de- nite farewell of clinical work. Indeed, such ap- ointments are now held by those making pathology specialty, in contradistinction to the old days hen these posts made the best of all trainings r the physician and surgeon, and the hospital irectly benefited.

A sketch is then made of the place which the riter thinks pathology should take in the medical urriculum, and the more important matter of the elation of the medical graduate to pathology is iscussed.

With regard to this question Mr. Macdonald says: "At present the clinician appears to be debarred to some extent from the requisite pathological training, and the consequences are bad for himself and bad for the pathologist, for the latter's time is often encroached on by work which should prop- erly be done by the clinician."

Again he says: "The clinical pathology depart- ment should be separate, and should deal with the reports on patients in the wards, from the patho- logical department proper, which at present is over- burdened with report work. The staff would con- sist, as at present, of the senior pathologist, who should be making pathology a specialty, and his assistants, who might be either going in for pathol- ogy or clinical work; but as I have indicated, the trained pathologist will always have a better claim for such posts and the clinicians are to a certain extent excluded. They could, however, become attached to the department as Fellows. The senior pathologist, relieved of his routine work, could apply his whole time to the superintendence of the thor- ough working up of the post-mortem cases. With his assistants and properly trained clerks and labora- tory boys every case might be thoroughly examined microscopically. At present it is quite impossible. An attempt should be made to allow of the junior assistant—physicians doing some of the post-mor- tems. This would give them opportunities which at present they do not have, and, moreover, a greater interest in the ward work."

The writer is of the opinion that the Carnegie trustees have made a mistake in the manner in which they have expended the money provided by the millionaire iron-master for Edinburgh University. He thinks that the cause of research would be much better advanced by the more liberal endowment of existing institutions, and above all by the providing of a sufficiency of trained technical assistants, than by the promotion of recent graduates to research appointments at £100 ($500), or £150 ($750) a year.

The point mainly urged by Mr. Macdonald as to the teaching of pathology in the majority of large medical schools is very pertinent under existing circumstances. The pathologist nowadays is a spe- cialist, and does not as a rule pay so much attention as formerly to grounding students in general pathol- ogy. The separation of pathology from medicine is to be deplored, for it is owing to this fact that the physician or surgeon has not received the training necessary to enable him generally to make a correct diagnosis from a microscopical and chemical stand- point. The ordinary medical student should have all facilities afforded him of gaining a competent knowledge of pathology, if not he cannot be properly equipped for the work before him.

Production and Inhibition of Glycosuria by Saline Solutions.

In the *University of California Publications*, M. H. Fischer gives some interesting results of experi- ments on this subject. Injection into rabbits of a $\frac{1}{4}$ molecular solution of sodium chloride, bromide, or iodide, produced polyuria, and usually glycosuria, the two conditions being, however, in- dependent of each other. The polyurial comes on 10 or 15 minutes after the beginning of the infusion, and lasts as long as it continues. The glycosuria begins, if at all, 1 to 4 hours after the beginning of the infusion, and lasts 6 to 8 hours. The amount of sugar rises steadily to 0.2 per cent., and then de- creases to zero, after which continued infusion ef- fects no further glycosuria. Less concentrated so- lutions than $\frac{1}{4}$ molecular produce no glycosuria, though they may produce polyuria. Also the latter occurs alone if to the $\frac{1}{4}$ molecular solution of sodium salts there is added calcium chloride. Further, once started, the artificial glycosuria is markedly lessened or checked by the addition to the infusion of as little calcium chloride as 25 c.c. of a $\frac{3}{8}$ molec- ular solution per 1000. On the contrary the ad- dition of sodium citrate increases sugar excretion. The amount of sugar and quantity of the urine bear no relation to each other, and vary indepen- dently. Albuminuria was a frequent, but not a con- stant, accompaniment of the glycosuria. In those animals in which no glycosuria occurs on the in- fusion of a $\frac{1}{4}$ molecular sodium chloride solution, the addition of a small amount of sodium citrate brought about the excretion of sugar. A consid- erable latent period exists before the solutions begin to produce or to check glycosuria, calcium chloride taking 30 to 60 minutes to check it, and a pure sodium solution requiring an hour or two to reës- tablish it. We thus have here again the same con-

tradictory antagonistic effect upon the tissues between the sodium and the calcium salts that Loeb has shown to exist in the case of the neuromuscular tissues.

The Treatment of Asthma by Intratracheal Injections.

Asthma is no doubt a disorder of varied origin and probably also of varied mechanism. In some instances the disturbance may reside in the bronchial mucous membrane, in others in the vascular apparatus. At times the exciting influence may have a direct or local effect, at other times an indirect or reflex effect. The treatment will vary accordingly, and may appropriately be both local and constitutional. The first indication usually is to relieve the paroxysm, and this can be most effectually done by means of a hypodermic injection of morphine and atropine or hyoscine. Then any discoverable exciting cause should be removed, if possible. This may be found to consist in vegetal emanations, in disease of the upper or lower air-passages or derangement of the bodily metabolism. Not rarely a definite etiological factor cannot be made out and the treatment must in large measure be empiric. Mr. Colin Campbell (*Liverpool Medico-Chirurgical Journal*, January, 1904) speaks in terms of warm praise of a procedure that he has employed successfully for more than nine years, both for the relief of the acute symptoms and for the prevention of their recurrence, namely, intratracheal injections. For these purposes he relies mainly on menthol, glycerin, and gelatin, although many other drugs are available when special indications are present, notably the salicylates. The menthol is believed to relieve the spasm of the bronchioles, the glycerin to stimulate the secretion of the mucous membrane, and the gelatin to dissolve the sputum. Large doses may be employed, up to 30 grains of the menthol and up to two ounces of the glycerin. Complete relief is said usually to follow the first injection, although more may be required and the treatment may need repetition in successive years.

The Relation of Pathological Conditions of the Choroid Plexuses to Mental Diseases.—George Ashton asks, are pathological changes present in the choroid plexuses of the insane? Are they more pronounced in any particular insanity? In what way may they influence the course of mental disease? We answer that pathological changes are present. The pathological changes most frequently met with are: (1) Hyaline degeneration. (2) Increase of the fibrous tissue. (3) Cystic degeneration. Pathological changes are most marked in the choroid plexuses from cases of general paralysis of the insane and senile dementia. They are present, but not so markedly, in cases of epileptic insanity, chronic mania, and chronic melancholia. They are least marked in cases of acute insanity. The choroid plexuses from our only case of congenital idiocy showed marked pathological changes. There are four possible functions of the choroid plexuses: (1) they may act as reservoirs for excess of blood in the brain; (2) they may secrete cerebrospinal fluid, or some of the constituents of that fluid; (3) they may absorb cerebrospinal fluid, or even possibly act as excretory agents for some of the constituents of the fluid; (4) they may have an internal secretion. The author does not for a moment consider that pathological changes in the choroid plexuses are a primary factor in the causation of mental diseases. As a secondary factor, however, aggravating the original morbid process in the brain, and retarding or preventing its arrest, these changes may have an influence of the most potent kind. He is inclined to regard these changes in the choroid plexuses as playing a greater part in the pathology of mental aberration than has so far been ascribed to them.—*The Medical Chronicle.*

News of the Week.

The Manhattan Eye and Ear Hospital.—In a refe ence, in the issue of last week, to the financial dif culties of hospitals in this city, the New York E and Ear Infirmary was inadvertently called t Manhattan. The Manhattan Eye and Ear Ho pital is, we are informed, in excellent financ condition, and has not closed nor contemplates cl ing any ward for lack of funds. The hospital constantly filled, and through lack of accommod tions many are turned away who require attentic It has outgrown the old building, and it is the tention of the directors to sell the present site ju as soon as they succeed in completing the endo ment fund of $200,000, the income of which w be needed to maintain the increased expenses of institution of twice the present capacity.

Association for the Study of Tuberculosis.—A meeting of the Tuberculosis Committee (appoin at the Baltimore Exhibition), held in New York February 27, it was decided to refer to a lar gathering the discussion of the question relating organizations for the study of tuberculosis in t country. A meeting for this purpose will be h at the College of Physicians, Thirteenth and Loc Streets, Philadelphia, on March 28, at half-past th

Rival Hip-Dislocation Methods.—It is repor that Dr. Lorenz of Vienna will come to Phila phia to receive an honorary degree from the Jeffe Medical College on May 27. While in the city will assist at an interesting clinic which will be h at the Jefferson Hospital on June 6. To this cl will also come Dr. Albert Hoffa, the chief expo of the operative treatment of congenital dislocat of the hip. It is proposed that at the clinic diffe cases will be taken up and that Dr. Hoffa operate on at least one patient upon whom Lorenz method was not successful. It is expec that Mr. Noble Smith of London and Mr. Rob Jones of Liverpool will also attend the clinic.

The Newest Medicomatrimonial Bill.—Assem man T. F. Matthews, it is said, will shortly in duce at Albany a bill providing that all per must obtain a physician's certificate before a m riage license can be issued to them. The bill, said by its author, is designed to place greater strictions upon the marriage of imbecile and h witted persons, and also to prevent those ha consumption and other diseases from marrying.

Imprisoned for Libelling a Quarantine Board.— Dr. J. M. Lindsey, President of the Internation Quarantine Board, an organization having for it object the advocacy of uniformity in State quara tine regulations, was found guilty on March 17 libeling the members of the Quarantine Board Mobile Bay. He was fined $100 and sentenced t ten days in jail. Dr. Lindsey published in Ne Orleans and Mobile newspapers last summer a article attacking the board, declaring it did n enforce its regulations faithfully and operated th quarantine for the money that was in it. H pleaded that his article was addressed to the boar and not to its members individually, and also tha its allegations were true.

The Inventor of the Laryngoscope Nearly a Cen tenarian.—Señor Manuel Garcia, to whom belon the credit of the discovery of the practical applic tion of the laryngoscope, entered upon his hun dredth year on March 17. The *British Medica Journal* records that he was born at Madrid in 180 When he was still a child his family were drive from Spain by the Peninsula war, and for a tim settled in Naples. There the elder Garcia studie the art of voice production, of which his son was t

come so distinguished a professor. Young Garcia's fancy at first turned to the sea, but in deference to his parent's wish he was trained for the operatic stage. He made his first appearance in New York. On his return to Europe he established himself in Paris as a teacher of singing. He has lived in London since 1850. The following is his own account of the invention of the laryngoscope: "Never being thoroughly satisfied with my own teaching, I longed to see a healthy glottis exposed in the very act of singing; but how could the mysteries of an organ so well hidden be revealed? One day in the autumn of 1854 I was strolling in the Palais Royal, preoccupied with the ever-recurring wish, when suddenly I saw the two mirrors of the laryngoscope in their respective positions as actually before my eyes. I went straight to Charrière, the surgical instrument-maker, and asking if he happened to possess a small mirror with a long handle, was supplied with a dentist's mirror. Returning home I placed against the uvula the little mirror (which I heated with warm water and carefully dried), then flashing on its surface with a second mirror a ray of sunlight I saw at once the glottis wide open before me, so fully exposed that I could see a portion of the trachea." More than twenty years before Babington had devised an apparatus similar to that used by Garcia, but he had never examined his own larynx as the Spanish *maestro* did. For several years after the date of Garcia's paper the laryngoscope was treated by superior persons as a "physiological toy." Its scientific and practical possibilities were brought home to the profession by Czermak of Budapest, who undertook a missionary expedition to the chief medical centers of Europe to demonstrate the uses of the instrument.

An Iowa Hospital for Inebriates.—The Iowa State Senate has voted an appropriation of $125,000 for the location at Knoxville of a hospital for habitual drunkards. This is the first open approval of Iowa's so-called "diplomaniac law." This law, which went into effect two years ago, has been severely criticised.

Water Legislation.—The Ohio Legislature has passed a bill giving cities the right to protect rivers from sewage for twenty miles above the intake of their water supply. In Cincinnati certain sewage is said to be emptied above the present intake of the water works, and a resolution was proposed by the City Solicitor that any connection, direct or indirect, for water-closet or vault purposes with any sewer, drain or system of sewers draining into the Ohio River above the intake of the water supply of the city, and the maintenance of any such connection after thirty days from the going into effect of the order, be prohibited. Action was delayed until after investigation.

A Physicians' Office Building.—The experiment of devoting the Sydenham Building to physicians' offices is one that is being watched with considerable interest. The owners have put the matter of selection of tenants into the hands of a committee of physicians, and it is said that of the first fifty applicants for suites only twenty-eight were admitted. It is the intention of the committee to make the building as nearly like a private residence as possible, and to allow in it nothing whatsoever of a commercial nature, although there has been considerable pressure brought to bear by druggists and instrument makers desiring to open shops in the building.

Koch in South Africa.—According to the Berlin correspondent of *The Lancet*, it is rumored that Professor Koch intends to resign his appointment as chief of the Royal Institution for Infectious Disease and to settle in South Africa. This conjecture no doubt originated in connection with the repeated and prolonged visits which he has made to Cape Colony and the other British colonies in Africa on the invitation of the Colonial Governments. The rumor in question is, however, unfounded. Professor Koch has gone to South Africa by special permission of the Emperor, and his place at the above institution will be preserved for him till his return. It is true, the correspondent adds, that Professor Koch has no objection to be absent from Berlin, his relations with the medical faculty there not being very cordial for reasons which are of a personal rather than of a professional character and are not of recent date. If he contemplates retirement, it is certain that nothing will be decided till his return, which is announced for the end of April.

Iroquois Memorial Hospitals.—The proposal of the Iroquois Memorial Association of Chicago to establish an emergency hospital in the building district in memory of the victims of the theatre fire has been indorsed by the Chicago Medical Society. The action of the society was embodied in a resolution presented by Dr. Andrew M. Harvey, and seconded by Dr. W. A. Evans. The preamble lays stress on the need of a hospital in the heart of the city, and the resolutions continue: "That the Chicago Medical Society approves the action of the trustees of the Iroquois Memorial Emergency Hospital in their generous effort to give to the people of Chicago a modern, fully equipped and endowed hospital capable of rendering prompt assistance to those cases of unexpected injury and sickness which are of daily occurrence;" and further, "That we, as a society, tender to the hospital our counsel, advice, and professonal service whenever required." We understand there is also another hospital to be erected as a memorial of the Iroquois Theatre fire. The institution, which, it is said, will cost half a million dollars, and is to be one of the finest in the world, will be known as the Chicago Homœopathic Hospital. William H. Hoyt and Richard T. Crane, who lost relatives in the fire, are the principal contributors.

Sale of the Mount Sinai Hospital Site.—The Appellate Division of the Supreme Court recently decided that Mt. Sinai had no marketable title to the land upon which its old hospital was built, and consequently an agreement to sell the same for $425,000 was void. The property was originally part of the common lands of the city, and was leased to the hospital corporation for a term of ninety-nine years, at a rental of $1 a year, to provide a site for a hospital which was to be used for benevolent and charitable purposes, and without discrimination as to race or creed. When the corporation decided to move uptown, it petitioned the city for leave to sell the Lexington avenue property. The petition was granted and a deed was made conveying the property absolutely to the hospital corporation, with leave to sell on condition that the proceeds were to be devoted solely to carrying out the aims and objects named in the corporation's charter. At the same time, the city made a contract to pay sixty cents a day for every free patient cared for in in the hospital. The court set this grant aside, holding that no good consideration passed between the city and the hospital, and that the grant was not a legal appropriation for a charitable purpose, since there was no provision for its control by the State Board of Charities. To relieve the hospital of its embarrassment a bill has been introduced in the State Senate authorizing New York city to

sell the property to the Mt. Sinai Hospital in consideration of an agreement by the hospital to grant free dispensary treatment to not less than 500 of the poor of the city each year for five years.

Cincinnati Academy of Medicine.—At a regular meeting, held March 14, the newly elected president, Dr. S. P. Kramer, was formally given the chair and delivered an address. This was followed by a business session and refreshments.

Order of St. Joseph to Erect Hospital in Chicago.—Plans for the Hotel Dieu, a religious hospital to be built for the hospitalers of St. Joseph, who came here from Kingston, Ont., has been prepared by Architect George A. Beaudry. The building will be erected at the corner of Harvard avenue and Sixty-fourth street, and will be four stories high, covering an area of 165 by 175 feet, and be of fireproof construction. The exterior will be of Bedford stone, with tiled mansard roof, above which will rise an ornate dome 68 feet high. In the halls there will be enameled brick wainscoting with marble and mosaic work, and the building will embody all the improvements that go to make up a first-class hospital. The cost is estimated at about $200,000. This, however, will be but a part of the building, which, when complete, will have a frontage of 225 feet and a depth of 175 feet. Rev. Bernard P. Murray, pastor of St. Bernard's parish, will have charge of the building.

Cincinnati Hospital Internes.—The annual competitive examinations for internes will take place at the Cincinnati Hospital on April 4, 5, 6, and 7. There are twenty-five candidates, of whom eight will be chosen for a service of eighteen months.

National Anti-Tuberculosis Association.—To prevent tuberculosis by legislation and through a campaign of education is the object of an organization incorporated in Springfield, Ill., recently, under the name of the National Anti-Tuberculosis Association. The incorporators are Dr. W. B. Metcalfe, Rev. F. M. Carson, C. W. Hanford, Alderman W. M. Butterworth, and Walter R. McDonough, all of Chicago. According to the incorporators the association is purely philanthropic. They expect to enlighten the public through lectures and publications, and to urge several important legislative measures that will check a spread of the disease. There is not a tuberculosis clinic in Chicago, and they mean to establish one in the downtown district as soon as possible. Several doctors are interested in the association, and the list of directors will show a large number of the prominent business men of the city. A campaign of education and for better legislation is needed to protect families. A hospital for the treatment of the disease may be established later.

Inspection of School Children.—The Board of Education of Chicago, through Dr. Henry Hartung, has formulated the following routine for the examination of school children: *Eyes.*—Diseases of the conjunctiva and lacrymal apparatus, muscles of the eyeball, visual acuity, hypermetropia, myopia, astigmatism. *Ears.*—External ear, auditory meatus, drum membrane, hearing, acute or chronic diseases of middle ear. *Mouth and Pharynx.*—Defects of tongue, lips, palate, condition of teeth, hypertrophy of tonsils, pharyngitis, adenoids, granulations, etc. *Nose.*—Acute or chronic rhinitis, nasal hypertrophies, polypus, deflection of septum, etc. *Chest.*—Abnormal development, round shoulders, spinal deflection, diseases of the heart and lungs. *Skin.*—Acute or chronic affections, scabies, pediculosis, favus, etc. *General Nutritional and Structural Disorders.*—Anæmia, chronic headaches, glandular enlargement, tuberculosis, deficiency of muscular development, nervousness, chorea, or any pathological condition which may retard the pupil's growth or influence his progress in school work.

The Henry Phipps Institute Lecture on tuberculosis, which was to have been delivered by Dr. Maragliano of Genoa on March 28, has been indefinitely postponed by reason of illness, preventing the lecturer from coming to America at this time. An abstract of the paper will be read at the meeting in Philadelphia to discuss the formation of a society for the study of tuberculosis, announcement of which is made elsewhere in this issue. The tuberculosis committee will be entertained at luncheon by Dr. L. F. Flick on the same day.

Dr. Rudolf Rapp has been appointed a member of the staff of the Craig Colony for Epileptics at Sayer, N. Y.

Long Island College Hospital.—The summer session at this school has been discontinued, the faculty having determined to lengthen the regular session in order to conform to the practice of other leading schools, into June.

A Röntgen-ray Congress is to be held in Berlin in the spring of 1905, to celebrate the tenth anniversary of the discovery of the *x*-rays. There will be an exhibition of *x*-ray apparatus in connection with it and with the German Surgical Congress.

Obituary Notes.—Dr. MOREAU MORRIS, who was Health Commissioner in 1866 and was up to the time of his death a special medical inspector for institutions the inmates of which are children, died on March 17 at his home in this city. He was born in Stillwater, Saratoga Co., N. Y., on June 19, 18[illegible] and was graduted from the College of Physicians and Surgeons in this city in 1848. He began practice at once in New York, and was appointed physician to a school for deaf-mutes, established by his father, and to the New York Juvenile Asylum. In 1[illegible] Mayor Hoffman appointed him Health Commissioner. Six months later the Metropolitan Board of Health was formed and Dr. Morris became a Sanitary Inspector. In 1869 he was made Assistant Sanitary Superintendent, and in 1870 became Sanitary Superintendent. He was for thirteen years surgeon of the Seventh Regiment and then of the Seventh's Veteran Association. He was at one time State Cattle Inspector.

Dr. FRANK K. IRVING, electrotherapeutist at the City Hospital, Newark, N. J., died in that institution on March 19, of pulmonary tuberculosis. He was thirty-five years of age, and was born in Fort Wayne, Ind.

Dr. WILLIAM FREDERIC HOLCOMBE died at the Presbyterian Hospital in this city, on March 17, at the age of seventy-nine years. He was born at Stirling, Mass., and was graduated from the Albany Medical College in 1849. For many years Dr. Holcombe was lecturer on diseases of the eye at the New York University Medical College and had been connected with the Eye and Ear Hospital, the New York Ophthalmic Hospital, and the Medical College for Women.

Dr. AMOS SEIP died at Easton, Pa., March 2[illegible] aged eighty-one years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1848, and had practised medicine for more than half a century when a stroke of paralysis, three years ago, caused him to retire from active work. He attained prominence during the cholera epidemic, in the Lehigh Valley in 1855, and was in charge of a soldiers' hospital at Easton during the Civil War.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING AT CAMBRIDGE UNIVERSITY—WINDSOR HOME FOR PATIENTS—MEDICO-CHIRURGICAL SOCIETY—METABOLISM IN FEVER—GYNECOLOGICAL SOCIETY, ANNUAL MEETING, TUBAL GESTATION, CURIOUS CAUSE OF IRRITATION OF BLADDER—BIRTH RATE—ASYLUMS BOARD—DUBLIN COLLEGES—A PATHOLOGICAL DEMONSTRATORSHIP—DEFENCE—NURSES' BILL—SAILORS' VISION—HOMELESS PEOPLE IN LONDON—LEAGUE OF MERCY—SIR S. WILKS—RECENT DEATHS.

LONDON, March 4, 1904.

Royalty is again to the fore in matters of medical interest. On Tuesday the King and Queen and Princess Victoria spent several hours at Cambridge, where town and gown vied with each other in displaying their loyalty. The visit was, as a matter of fact, academic in its object, but the popular demonstration was none the less enthusiastic. The King received three addresses, attended a congregation in the Senate House, and opened in succession the Law Library, Law School, Medical School, Botanical School, and the Sedgwick Museum, which last he unveiled the statue of the eminent professor after whom it is named.

A statement of the aims of the university in erecting the several buildings was read, in which His Majesty was told that they are a part of the policy on which the University entered long ago and which is not even yet consummated, to meet as far as possible the claims of science while also providing for the literary studies which have ever been dear to it.

Princess Christian on Saturday opened a new medical and surgical home for paying patients at Windsor. This her Royal Highness has founded in connection with a district and nurses' home as a memorial of her son, Prince Christian Victor. The establishment is equipped with all modern appliances.

On Wednesday the Princess presided at the seventy-fifth annual meeting of the Royal Free Hospital. Her Royal Highness is president of this valuable charity and expressed the greatest interest in its work. The chief event of the year was a bazaar organized by the Princess, which brought in £3116; but this sum will be required for the improvements in the arrangements for the nurses. The hospital is largely dependent on legacies—a very uncertain source of income. King Edward's fund increased its grant last year by £500 and gave £1500 for certain building improvements urgently required.

The annual meeting of the Royal Medical and Chirurgical Society was held on Tuesday. The report showed a credit balance for the year of £857. The entrance fee of £6 6 shillings has not hitherto included the first year's subscription. In future the sum is to be divided into £3 3 shillings entrance fee and the other £3 3 shillings will be for the first year's dues. The president, Mr. Alfred Willett, then delivered his address, which included the usual obituary notices of those Fellows who had died during the year. Votes of thanks were passed to the retiring officers and the incoming president, Sir Douglas Powell, took the chair.

At the previous ordinary meeting of this society, held on the 23d ult., a paper on "Metabolism in the Febrile State" was read by Dr. G. C. Garratt, giving the results of analyses of patients in the London Hospital during seven years. In the absence of pyrexia a nucleinic diet caused no retention of sodium or chlorine, but a small loss of nitrogen. Reduced urinary water was due to increased excretion by other routes. Reduction of chlorine occurred in all acute fevers except malaria. This reduction might continue far into convalescence, but bore no relation to retention of water. Sodium and chlorine given in other combinations were retained, and the return of one might not coincide with that of the other. That the chlorine was retained in combination with albumin seemed probable, but Dr. Garratt had not detected chlor-albumin in muscle after fever. Urea and uric acid showed the usual febrile increase without relation of phosphates. He concluded that endogenous uric acid came from proteids rich in nitrogen and sulphur but poor in phosphorus. Excretion of phosphorus and free acid tended to run parallel. Sulphuric acid increased out of proportion to urea. Potassium increased, but less than urea; it showed some parallelism with phosphoric and sulphuric acids and played the principal part in combining with them. Dr. Garratt therefore suggested that some of the increase did not represent metabolism of potassium-holding tissues, but the output of phosphoric acid was a better guide. The organism in fevers seemed to possess a power to select what proteids it would consume and to choose those rich in sulphur and nitrogen, sparing those rich in phosphorus and potassium. Calcium, like chlorine, was decreased during fever. Magnesium was much reduced at first, but increased later.

Captain Statham referred to the difficulty of eliminating error in estimating urea by the hypobromite process.

Dr. Spriggs suggested that ammonia, being always present in urine, was a normal product of cell metabolism converted into urea in passing through the liver. Blood which did not pass that way would lose its ammonia in the kidneys. In pyrexia the liver only converted part of the ammonia salts, so more was thrown on the kidneys.

Dr. Robert Hutchinson spoke most highly of Dr. Garratt's work and said he had changed his opinion on the decreased chlorides in consequence. Dr. Garratt had also shown that sodium might be retained, not as chloride, but in some other combination. The extreme difficulty of estimating metabolic processes from examination of excretions was further shown by this valuable paper.

At the Gynecological Society Dr. Wm. Duncan read an account of a case of rupture of a tubal gestation nineteen days after conception and ten days after the uterus had been curetted. He also showed the specimen, which the president (Professor Taylor) thought of extreme interest. He had himself described a case following curetting and remarked on the importance of excluding pregnancy before resorting to that proceeding. The patient was in such a state that transfusion was imperative before operation, and Dr. Duncan said it showed the necessity of taking the apparatus with one.

Mr. Spanton read a note on a cause of irritation of the bladder in girls. Some little patients of three to five years had suffered so much as to cause a suspicion of calculus, but none was found, and there was no albumin and no sugar—under the microscope, a few blood-corpuscles, mucous cells, phosphates, and urates. A few woolen fibers were detected in one case and in subsequent ones looked for. These were exactly like those of the child's combinations. These were changed for linen, and diluents were given freely, and in a few days all went well. In other cases Mr. Spanton was naturally on the alert. It is obvious that neglect in such a case might lead to serious complications and to the surgeon's discredit. I congratulate Mr. Spanton on his care and acuteness in detecting the origin of the trouble.

At this meeting the new president, Professor John Taylor of Birmingham, delivered his inaugural address, which he devoted to the "diminishing birth rate, its causes, tendency, and possible remedy." He showed that the rate is diminishing on the continent as well as in our islands, but not to the same extent. He also held that not only are our marriages less fertile, but that the children born are weak, neurotic, and inclined to alcoholism and crime. Further, the upper classes are becoming so sterile that the rising generation is being recruited from the more ignorant and vicious population. This, he said, was a "handwriting on the wall." He believes the chief cause to be the adoption of measures to prevent conception, and these unnatural practices he declares to be destructive to the life of the nation and race, as well as exceedingly injurious to the individual. He has known acute disease thus caused, but chronic illness is very common. Neurasthenia and brain-fag, he said, are too often cases of marital onanism. He declared that "there is no method of prevention that can be regarded as innocuous"; that the health and mental and moral stamina are undermined, and that the children "arranged for" in these artificially sterile marriages also suffer and are degraded by their antecedents. All this will no doubt seem shocking to the followers of Malthusian notions, but Professor Taylor is sure of his ground and says those in gynecological practice must know it. Some thirty-five years ago prevention was advocated by some admirers of Malthus and the French system. The notion "has spread like a blight over the middle classes," says the professor, and the "true wealth of the nation, the "full-breathed, bright-eyed, and happy-hearted children, of Ruskin have more or less gone down before it." Let us hope the less prevails over the more.

I have more than once called attention to the extravagance of the Asylums Board. The managers seem to be waking up to the fact that building schemes are costly and that the public is in earnest in remonstrating. Some genius among them has hit on a notable scheme of economizing—nothing less than to dismiss some of the junior medical officers; and as to the seniors—why, reduce their allowances of coals and candles, let them light and warm their own apartments and pay for the charwomen and porters' time! Truly a certain way of recouping tens of thousands of pounds wasted on bricks and mortar!

Some time since the presidents of the Royal Colleges of Physicians and Surgeons in Dublin were omitted from

the list of persons having the right of private entrée to levees and drawing rooms at the Castle. This was resented as an insult to the profession and unaccountable, considering the manner in which the Viceroy has acknowledged his indebtedness to it. I understand that His Excellency has directed the right to be restored.

A Riddell Demonstratorship of Pathology is to be established in Queen's College, Belfast, the sum of £5000 having been given for that purpose by the Misses Riddell. A tube of radium has also been promised to that college by Sir Otto Jaffe of Belfast.

The proposal of the restless section of the British Medical Association to undertake the defence of practitioners is exciting a good deal of opposition. We have two defence societies, as you know, and they might well amalgamate. But the British proposes to absorb both, and to give its members no benefit whatever, but to levy from them the same sum that the defence societies ask for the work they have done pretty well, on the whole, although there are exceptions.

Dr. Farquharson fathers the Nurses' Bill in the House of Commons. The nurses want to be registered—they do not know the uselessness of it—and the matrons want to be put on the proposed council and to be paid fees and traveling expenses as they may themselves from time to time allow.

Eyesight in the navy is beginning to demand more attention. The boys on entering pass a rough test, but afterward no examination is made, and yet it is between youth and middle age that visual trouble is apt to develop. When so much depends on accurate gunnery it is time to end neglect. One observer thinks that 30 per cent. of sailors are not improbably affected with some defect of sight, and suggests a fresh examination every time a ship is commissioned.

The Medical Officer of the County Council on the night of the 29th ult. conducted a sort of census of the Homeless persons in London, *i.e.* people who have not the means to pay for a night's lodging in the common lodging-houses or will not apply for poor-law relief. They pass the night in the streets, or under arches, or in the recesses of front doors, or on landings and staircases of tenements where the doors are left open. From the persons counted on the night named the doctor estimates that one in every 2000 of the population was homeless. The count was restricted to a limited area and there were more than 6000 vacant beds in the common lodging-houses that night.

Yesterday, on the invitation of the Duchess of Somerset, a number of ladies and gentlemen of North Kensington met and formed a branch of the League of Mercy. The Duchess expressed her pleasure at meeting so representative a gathering and commended the work of the League, which was found to assist the hospitals through the medium of the King's fund. Her Grace added that as the Countess of Chesterfield had been so successful in another part of Kensington she felt sure they would not let North Kensington lag behind.

I am glad to report that Sir S. Wilks has improved during the week.

Among recent deaths I may mention the following: Jas. Smith Turner, M.R.C.S., L.D.S., consulting dentist to the Middlesex Hospital, one of the leaders of dental reform who helped the late Sir John Tomes to obtain the Dentists' Act (1878), which has done so much to raise the dental branch of the profession.

Charles Godson, F.R.C.S., of Barnet, at the ripe age of eighty-four, a kindly, courteous gentleman, who had retired from practice above twenty years. The statistics of his midwifery practice for thirty-five years, compiled by his son Clement, may be seen in the *Obstetrical Transactions*, 1877. There were only 7 deaths in 3223 deliveries.

George Niven, M.A., Aberdeen, M.B. Cambridge, of Manchester, aged only forty-five. He was one of four brothers who have all made a notable record.

General Sepsis from Wounds.—If the septic process has invaded the system, the use of antistreptococcus serum is very valuable, in full dose of 10 c.c., repeated once or twice in twenty-four hours. In punctured wounds with a valve-like opening the wound should be freely opened to the bottom and cleansed. In gunshot wounds of the abdomen the only thing is immediate laparotomy and suturing up of the perforation. In wounds of the chest, provide drainage and wait for Nature to cure, unless there are clear and urgent reasons for operation. The same is true in wounds of the skull and brain, with rigid asepsis and the removal of all spicules of bone.—LATHROP.

THE PSYCHICAL RELATIONS OF TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In a recent letter published in your journal (Febru ary 13, 1904), Dr. S. A. Knopf reiterates the assertio which he made in his article, "A Plea for Justice to th Consumptive" (MEDICAL RECORD, January 2, 1904) tha I am a "phthisiophobe," because I believe all consump tives to be criminals or insane. In this renewed attac upon me, Dr. Knopf again bases his assertions upon tw sentences from my article on the "Psychical Relations o Tuberculosis" (*New York Medical Journal*, August 1 an 8, 1903), in spite of my explicit denial, which you wer good enough to publish in form of a letter in the MEDICA RECORD for January 23, 1904.

With all due modesty, and with all due respect to D Knopf and the Standard Dictionary which he (somewha irrelevantly) quotes in his letter of February 13, I sti retain the mastery of my own thoughts, and reserve th right to demand that my utterances shall be interprete according to the canons of English and the laws of log before they are made the subject of controversy. Fortu nately for me, however, Dr. Knopf lays bare in his lett the method whereby he has arrived at the conclusion tha I am a phthisiophobe and regard all consumptives, or a average consumptive, as insane or possessed of crimin tendencies. Let the reader judge for himself:

Dr. Knopf bases his whole ingeniously wrought stru ture of casuistry upon the following sentences which h quotes *verbatim* from my article: (1) "To me this accou shows the germination of a homicidal tendency which the resultant of the psychical defects which I have ou lined in my analysis of the average consumptive's men peculiarities." (This sentence, as Dr. Knopf must kn if he has read it carefully, does not mean that the ho cidal tendency is seen in the average consumptive, b that it was apparent *in this one case*, to which I refer the words "this account." It means further that I beli that this tendency was the resultant of those psychi traits (neurasthenia, psychasthenia, etc.) which I outlin in another part of the article under the heading of "t mental peculiarities of the average consumptive.")

(2) "Here (*i.e.* again *in this case*) psychasthenia, t loss of self-control, and the rise of brute selfishness ha combined to distort the clearness of ethical perceptio

To these quotations from my article, Dr. Knopf ad the following comment: "Now in the Standard Dictio ary the word 'average,' when applied to persons in t sense, is defined as *possessing general or typical charact istics*. Thus, according to Dr. Saxe's conclusions, t general and typical characteristics of a consumptive i psychasthenia, the loss of self-control and the rise of bru selfishness, *resulting in a distortion of the clearness of e cal perception*." (Italics mine). Thus, by simply substitu ing the equivalent of the word "*average*" taken from t first sentence, for the word "*here*," my second sentence made to mean what Dr. Knopf wishes it to mean for h own purposes. The homicidal tendency which I cite this case (of a man who deliberately spat everywhere t that his wife may not survive him) was spoken of by m as the resultant of certain fundamental changes in th mentality of the consumptive—changes which in t average case are manifested, as I took care to state, b petty exhibitions of selfishness, by loss of self-contr (peevishness; irritability of temper), etc., but which *this instance* have been raised to the higher potencies of mental disorder and intensified into a state in which t clearness of ethical perception is distorted. Nowhere I say, I repeat, that a greater tendency to crime has be noted among consumptives than among normal indiv uals, nor that the average consumptive exhibits a d torted ethical perception. I certainly do *not* say it in t final sentence which Dr. Knopf quotes from my conc sions, and which merely summarizes the traits which ha been noted by the foremost authorities who have writt on the subject, of the mentality of the typical consum tive. For these ideas I neither claim originality nor as my own authority, but every statement I have made supported by the testimony of writers of internatio reputation—the weight of whose opinion even Dr. Kn must acknowledge.

I have quoted here in detail, because I wished yo readers to see exactly to what lengths Dr. Knopf w obliged to go in order to extract the desired meaning o of my article. And even those who have not read m now much-discussed modest effort, but who have obtain their information regarding it from Dr. Knopf's arti and letter, will now realize the situation. I think I ha proved to any unbiased man who has followed this co troversy that Dr. Knopf's tirade against me had no fou dation and that his arguments utterly collapse on critic review. However this may be, the personal elemen upon which Dr. Knopf lays so much stress, is to me sub

rdinate to the real question at issue which I am glad to ave raised—the question as to the relation of tuberculosis and crime and as to the ethical necessity of exercising clemency in consumptive criminals. This is a matter r investigation by expert criminologists and alienists, nd I have no doubt that a great deal of light will be thrown n it from this quarter within the next few years. Dr. nopf himself cannot pretend that he has spoken the last ord on this subject. So far as I am concerned, the phthisiophobia" and the other crimes which he lays at y threshold no longer require discussion.

DE SANTOS SAXE, M.D.

394 WEST NINETY-SECOND STREET, NEW YORK.

SPONDYLOZE RHIZOMÉLIQUE.

TO THE EDITOR OF THE MEDICAL RECORD:

R: In the issue of the MEDICAL RECORD of February , 1904, there is an article by Dr. Alfred Gordon of Philelphia entitled "Contribution to the Study of Spondye Rhizomélique, with Report of Three Cases," which tains the report of a case which, it seems to me, should t be admitted to this category. As the case in question the most important one reported by Dr. Gordon, and, it seems to me, there is no justification for calling it a tribution to spondyloze rhizomélique, I should like to Dr. Gordon through your columns why the case is not ost typical one of amyotrophic lateral sclerosis. The ts of the case as he records them are: A fifty-four-r-old negress developed (1) vertigo, attended with loss consciousness; (2) difficulty of speech; (3) stiffness of spine and the extremities; (4) disturbance of the incters; (5) spastic ataxic gait; (6) mask-face due to ticity of the muscles; (7) joints stiff but not enlarged, ient moves *tout de pièce*. The objective symptoms e: (1) Argyll-Robertson pupils; (2) some ataxia of the er and lower extremities; (3) tremor of the upper remities; (4) exaggeration of all the tendon-jerks; (5) inski jerk; (6) increased mechanical irritability of all voluntary muscles; (7) muscular atrophy of the appear-e and distribution of the type Aran-Duchenne; (8) ing sensations in the legs and girdle sensation about thorax; (9) no objective sensory disturbances; (10) nounced general arterial sclerosis. The rigidity, ataxia, iculty of mastication and of speech, wasting and weak-s increased, swallowing became difficult, incontinence eased, bed-sores developed and the patient died, the se having lasted between one and two years. If this ot the classical picture of amyotrophic lateral sclerosis sibly of syphilitic origin because of the Argyll-Robert-pupils, although such pupils occur, I believe, occa-ally in cerebral arterial sclerosis), then the description s in our books is all wrong.

would not trespass to this extent upon your space e it not that the subject of spondyloze rhizomélique n important one, whose etiology and pathogenesis are ood as unknown, and it is essential that at this stage our knowledge no contribution tending to add to its curity be permitted to pass unchallenged.

JOSEPH COLLINS, M.D.

ew York.

PHYSICIANS PREVENTED USING THE LIBRARY OF THE ACADEMY OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD:

IR: By a new rule of the Academy of Medicine Library, ysicians of this city, who are not members of the acad-y, are considered merely as members of the general blic, and are now prohibited from the use of the library cept three and a half hours daily at a most inconvenient e, from 9.30 A.M. to 1 P.M. It seems to me that this a great injustice to the medical public, and will now t the scope of medical education. I feel reasonably e that those who have given financial support, and other-e in the form of bequests to the library fund, certainly pected the general medical public to have access to this uable library. Furthermore, I am convinced that those o contemplate giving to the library fund may hesitate they know that the medical profession has so little portunity to use the library. Personally my office hours e up the whole morning, and no doubt there are hun-eds of others similarly situated, who will be debarred m the use of the library. On a recent visit to the rary at 5.30 P.M., I was refused admittance on account non-membership. It was important that I should con-lt a reference book, and I endeavored to be admitted as guest of one of the two occupants of the library. The endant would not permit it. However, after considerable parley, I was allowed to remain when one of the mem-rs of the academy insisted upon it. By this new rule would appear that the value of the library is lessened, nd the attendance much smaller, as evidenced by the afternoon when I was present. At this time there were but two readers in the library.

Formerly the general medical public had access to the library from 10 A.M. to 6 P.M., and members of the academy had the same hours, with the added privilege of the exclusive use of the library in the evenings.

SAM'L G. TRACY, M.D.

NEW YORK.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 3, 1904.

A Case of Traumatic Hæmopericardium.—John Lovett Morse reports this unusual case. The patient was a girl two and a half years old. About a month before the writer saw her she had fallen on to a needle which was on the window-sill. The needle broke off, about half of it remaining inside the chest. It penetrated the chest near the right edge of the sternum. She seemed well for about two weeks. She began to ail at this time, although her symptoms were rather indefinite. She breathed hard, the respiration often being grunting in character. She complained of pain in the side. Physical signs and fluoroscopic examination showed effusion in the pericardium. It was tapped and aspirated. Bloody fluid was obtained by this procedure. The child was much relieved by this operation and in a few days was discharged well. This hemorrhage must have been due to a lesion of the pericardium caused by the needle. The needle probably did not reach the pericardium at first, but later worked its way to it. It is not easy to explain the comparative mildness of the symptoms with such a large effusion. Probably the greater part of the pressure of the fluid was exerted on the liver and diaphragm. At operation, the needle was first introduced into the fifth right space just at the edge of the sternum. The results show that the pericardium can be safely and successfully reached in this situation.

The Relation of Some Special Causes to the Development of Neurasthenia.—Robert T. Edes believes that it is possible without straining facts to accept the view that neurasthenia is not merely a name to cover want of classification, but is a fairly well-defined condition, if not a distinct disease, and has a real pathology. Neurasthenia is a state of diminished energy of the nervous centers, especially the higher psychical, closely akin to ordinary fatigue, only of such extreme development as to have caused incapacity for rapid restoration. Neurasthenia is a paresis of the attention and will, the result of long-continued overfatigue. Apparently the simplest, most obvious and most often assigned cause for neurasthenia is mental overwork, and in the cases of the young, overstudy. It is when there is added to excessive work, responsibility, worry, ambition, failure of attainment of the object striven for, and the like, that neurasthenia often develops. Even monotony is sometimes more wearing than some forms of mental labor. Extreme muscular fatigue renders one incapable for a time of doing his best mental work. The coincidence of neurasthenia and sexual abnormality of any kind cannot be considered proof that the former is the result of the latter without further inquiry. The causation may be in the other direction. Abnormalities of all kinds are well-known accompaniments and symptoms in many neuropathic conditions as well as in actual insanity. Symptoms of difficult and imperfect digestion are among the most frequent among what may be called the secondary ones of neurasthenia. They aggravate it and are caused by it, and thus an obstinate, vicious circle is produced. There has been much discussion concerning the connection between ocular defects and neurasthenia. The writer says that it is conceivable that any one of these important conditions, if brought to bear upon a system which is by birth or education of impaired resistance, should by itself be applicable to all cases of neurasthenia as the sole cause. It is of course equally possible that all should be present in only one case, but the probabilities are immensely against either of these extreme alternatives. The general practitioner or the neurologist to whom these patients go, should be able to follow the most important clues far enough to be able to decide when it is necessary to call in a specialist.

Journal of the American Medical Association, March 19, 1904.

Examination of the Blood of Pneumonia Patients for Pneumococci.—Fifty cases are analyzed in the paper presented by F. C. Kinney. He concludes that the germs can occasionally be found in the blood at any time during the disease. In one series of twenty-five cases the pneumococci were found in 12 per cent. In a second series of the same number of patients and with a method more favorable for the growth of the organism, they were found in 76 per cent. The best results as to their presence are obtained by using large quantities of blood with a

dilution of over one to twelve of a liquid culture medium, preferably bouillon. The technicalities of the method are given in detail. The mere finding of the organism is of no prognostic value. Of nineteen positive cases in the first group 69 per cent. recovered, while of the negative cases 33 per cent recovered. But when the germ was found in the blood of a patient who subsequently died, it was invariably present in large numbers.

The Use of Silver Foil to Prevent Adhesions in Brain Surgery.—The use of this material is commended by M. L. Harris, who reviews the literature of the employment of this class of substances and adds illustrative cases from his own experience. Regarding the technicalities of the method, he notes that the traumatism incident to the operation should be as slight as possible. A bone flap which can be replaced is preferable, when possible, to the trephine opening with the bone left out. Before the introduction of any substance hemorrhage should be perfectly controlled and all blood-clots removed. The substance should extend well beyond the edge of the area involved in the adhesions. There should be no openings or breaks in the substance. The material must be one which can be sterilized. The wound must heal in a perfectly aseptic manner.

A Method of Dispensing with Rubber Gloves and the Adhesive Rubber Dam.—J. B. Murphy advises the use of an impermeable coating, preventing the escape of skin secretions and preventing the entrance into the pores and srevices of the skin; a coating which will not impair delicacy of touch or the pliability of the skin. The preferable preparation is one of from 4 to 8 per cent. of gutta percha in benzine or acetone. He has found from a four months' experience that the 4 per cent. benzine solution is the most serviceable for the hands, as it wears better on the tips of the fingers under handling instruments, sponges, and tissues than the acetone solution. For the abdomen the acetone solution has the advantage, as it dries in from three to four seconds after its application, while the benzine solution takes from two to three and a half minutes to dry to a firm coating. The acetone coating when dry is only slightly adhesive while the benzine coating is sticky. The method of application to the hands and forearms is that of simple washing, as with alcohol, care being taken to fill in around and beneath the nails. The hands must then be kept exposed to the air with the fingers separated until thoroughly dry. They may then be washed in alcohol, bichloride, or any of the antiseptic solutions without interfering with the coating or affecting the skin. It wears off on the tips of the fingers if the operations be many or prolonged, when another application may be made between operations; on the remaining portion of the hands one application is sufficient for a whole morning's work. Washing in benzine after the surgeon has finished his work leaves the skin soft and smooth.

Medical News, March 19, 1904.

Forensic Eye Aspects of Tabes.—Jas. G. Kiernan states that the Argyll-Robertson pupil exceptionally occurs in many conditions. It has been temporarily noted after railroad accidents and other shocks, in cases in which no subsequent evidence of grave neuroses had occurred. In such cases it disappears. Exceptionally it has been found in alcoholism. It occurs early in locomotor ataxia, in paretic dementia, and in constitutional syphilis. But constitutional syphilis occurs quite often in which it is absent. It is frequent in parasyphiloses. But it is not to be taken as a pathognomonic mark of these conditions, since it has been found in conditions like alcoholism, and therefore may be a temporary expression of toxic states occurring during constitutional syphilis.

The Individual Equation of the Patient in Surgical Operations.—W. L. Estes states that some patients are particularly liable to microbic inoculations. They are very apt to die from very mild forms of sepsis after operations. It goes without saying that the environment and habits of the patient have much to do in determining the result of an operation. Vegetarians do not stand the loss of blood well. Meat eaters do not generally stand general anæsthetics well. The disposition is bound to affect the outcome of an operation. A cheery spirit has a markedly favorable influence. The extremes of age increase markedly the bad prognosis of an operation. Nationality makes little difference. The physical condition of the patient ought to be carefully determined. Organic diseases of the viscera greatly modify the prognosis of operations. The two regions that seem to be especially unfavorable for extensive operations are the base of the brain and the thoracic cavity. The surgeon should do all he can to prevent disease. Temporizing in surgery will not do. When an operation is necessary, it should be done at once.

The Clinical Significance of Pain in the Epigastrium.—Frank H. Murdoch declares that pain in the epigastrium may be due to hyperacidity, hypersecretion, hyperæsthesia of the stomach, nervous gastralgia, biliary colic, certain affections of the spinal cord, cancer, gastric ulcer, pancreatitis, some forms of appendicitis, and Addison's disease. The pain of hyperacidity comes on one or two hours after meals and ceases at the end of the digestive period. It may be temporarily relieved by the ingestion of food or alkalies. The pain of the periodic hypersecretion comes on suddenly in the midst of perfect health. Besides pain, there is extreme thirst and vomiting of large quantities of hot, sour gastric juice. In hyperæsthesia of the stomach the pain appears immediately after eating. In nervous gastralgia the pain is intense, either sharply localized or diffuse. In biliary colic the attacks appear only at intervals, and have no relation to the taking of food. The attacks are sudden and are apt to be followed by jaundice. In cancer of the stomach, pain is the most constant of all the symptoms. It does not depend upon the taking of food. The pain of gastric ulcer usually comes on from ten to twenty minutes after the ingestion of food, and disappears at the completion of gastric digestion. There is often intense pain in the epigastrium in Addison's disease. The weakness, however, characteristic of the disease appears before the pain.

New York Medical Journal, March 19, 1904.

The Dangerous (?) Operation of Uterine Curettage.—D. H. Craig criticises the views expressed in a recent paper by Van de Warker, claiming that uterine curettage is perfectly safe in the hands of those qualified to practise surgery. It is not a minor operation, however, and calls for quite as much judgment and skill as do many operations usually considered much more formidable. He objects to the use of a triple-clawed volsella, and deprecates too forcible traction on the uterus. Adequate dilatation must be secured. Assuming modern asepsis to be maintained, he considers the greatest danger to be perforation of the uterine wall. The avoidance of this complication begins with the second step in the actual operation. The cervix is grasped with the volsella or bullet-forceps, *after the scrubbing and disinfection of the vagina is completed, never before*, and the next step should be the determination by the probe or sound of the exact shape and depth of the uterine cavity. If this step is never omitted there is no danger of perforating the wall of the flexed, non-puerperal uterus, which much more often occurs in inserting the dilating instrument than with the curette. He advises against the post-operative tampon. Absolute asepsis is probably never attained, and gauze furnishes a mesh in which the oozing blood will clot instead of draining away by gravity. Moreover the withdrawal of gauze is apt to deposit septic matter on the fertile soil of the abraded surfaces. Douching should be avoided for forty-eight hours. If a douche is ever demanded, saline solution or sterile water should be preferred.

The Inaccuracy of the Common Spoon as a Milk Sugar Measure in the Home Modification of Milk.—Attention to the inaccuracy of the spoon measure is called by J. M. Miller, who states that the amount of milk sugar contained in a level teaspoon, as measured by three different persons, weighed respectively, 55, 85, and 90 grains, and a level tablespoon 168, 215, and 195 grains respectively. In answer to the objection that with such an inert substance such variations are of little moment he replies that in weakly children the variation may be of great importance. He therefore advocates the use of a small box measure instead of a spoon. Such measures are insisted on by the most careful writers on pediatrics.

Post-operative Pneumonia.—The patient of L. E. Holmes, a boy of nineteen years, was operated on for sarcocele and phimosis, unilateral castration and circumcision being performed. Two days later pneumonia developed without apparent cause. The case ran a somewhat prolonged course, but the patient was discharged well on the twenty-fifth day after the operation. A possible cause of the lung lesion might have been the aspiration of mucus during the anæsthesia (ether), but it could not be absolutely proven. The author discusses the various causes of post-operative pneumonia. No one causal theory will explain all cases. The lesion is more often of the lobular type, rather than the lobar. There is a special danger in operations done by artificial light (electricity excepted) when chloroform is employed, for a poisonous gas is formed by the combination of chloroform vapor with carbon monoxide. The literature of this latter phase of the question is reviewed with some detail. Pneumonias follow with about the same frequency with both ether and chloroform, but a general anæsthetic does not materially increase the danger of post-operative pneumonia if the lungs are in a healthy condition. We should

be sure that we are using a pure drug in a clean inhaler, should give the anæsthetic with the greatest care, in as small quantities as possible for the maintenance of a proper narcosis, and after operation should always keep the patient's head low, changing the position of the patient frequently in order to avoid hypostatic congestion.

American Medicine, March 19, 1904.

The Problem of Potassium Iodide.—Alfred Gordon calls attention to the usefulness of the iodides in the treatment of cerebrospinal syphilis. The idiocyncrasy of the patient should be first tested. Small doses of the drug are given, say, 0.32 gm. (5 gr.) three times daily for an adult. The dose should be increased every other day, 8 gr., then 10 gr., three times daily, and so on. The patient must be seen often, and at the slightest symptoms of intolerance the drug should be discontinued for one or two days and the same plan again followed. There is no possibility of establishing a maximum dose. The writer has used sodium iodide instead of potassium iodide in the majority of his cases.

Occurrence of Diabetic and Non-diabetic Glycosuria in the Same Individual.—Heinrich Stern presents the following conclusions from his work on this subject: The diabetic state may be well established before glucose is excreted by the urine. Diabetic glycosuria is nothing more than the salient feature of the second stage of the diabetic deterioration. Glycosuria is a symptom, an enunciation of manifold other disturbances of ectogenous, as well as endogenous causation. With the assistance of various concrepant factors we are enabled to differentiate clinically between the diabetic and non-diabetic form of glycosuria. Complex melituria is the result of two concurrent or interdependent affections of dissimilar character, having the one symptom, glycosuria, in common. The recognition of complex melituria depends upon the alternate prominence of one set of symptoms, including the respective glycosuria.

The Ochsner Treatment of Appendicitis after Operation.—George S. Brown gives a series of cases and the method of post-operative treatment. Lavage, tight binder, opium, plenty of water to drink and no purgatives until the bowels manifest a disposition to move by the uncomfortable rolling about of the gas and the other symptoms showing that the inflammation is subsiding and the paralysis of the bowel is being overcome. Irrigation of the stomach and bowels will favor quiescence of the bowel and the formation of adhesions. By using the binder properly—keeping it tight as the gas recedes, opium can be used liberally, for its quieting influence on the nervous system and conservation of the patient's strength. Irrigation, when sufficiently prolonged, will not only empty the stomach of ether-laden mucus, but will wash every particle of ether out of the blood. The writer gives his patients all the water they want, both before and after ether, and has had only good results from the practice. If there is nausea, vomiting cures it in a little while if the patient is given water.

The Lancet, March 12, 1904.

The Treatment of Incontinence of Fæces by the Subcutaneous Injection of Paraffin.—Two cases are reported by H. Burgess. He would divide such cases into two groups: (1) Those in which the sphincter retains some power, but cannot close the canal entirely. It is conceivable that if by introducing paraffin into the submucous tissue on the inner surface of the sphincter we narrow the lumen of the bowel at this situation and thereby diminish the work which the sphincter has to perform; even a weakened sphincter may be able firmly to occlude the remaining lumen and so to render the patient continent. (2) Those cases in which the sphincter is completely paralyzed, as in many nervous diseases, or has been entirely removed, as after the operation of excision of the rectum. Various plastic operations have been devised, but at times no one seems to meet the emergency. In these exceptional instances the paraffin injections may relieve the difficulty.

An Inquiry into the Source of Scarlatinal Infection and Its Bearing in Hospital Treatment.—R. E. Lauder briefly reviews the anatomy of the mucous lining of the upper air tract, and notes how easy it is for modification in its physiological integrity to allow of the reception and development of various infections. This tract is the focus of trouble. He then goes on to detail the mode of treating the disease in his own hospital, finding it possible thereby greatly to lessen the occurrence of albuminuria enlarged glands, aural and nasal discharges, etc., and also to reduce the duration of the fever and length of confinement to bed. The method referred to has to do with practical hospital details, and must be consulted in the original paper by those interested. He thinks that too much stress has been put upon "feeling" *per se*. A more rational plan is to care for the upper air tract of convalescent patients, particularly with reference to the checking of nasal and aural discharges.

The Congenital Origin of Hernia.—R. H. Russell notes that congenital hernia ordinarily signifies an oblique inguinal hernia into a funicular process which is unobliterated throughout, so that there is no barrier separating the abdominal peritoneum from the tunica vaginalis. It was not understood that the hernia was present at birth, but that it had entered a congenital sac. It was considered that the inguinal hernia in which the sac was found to be distinct from the tunica vaginalis might be safely relegated to the category of acquired hernia, and acquired hernia implies that the sac is not a developmental structure and is not therefore present at birth, but that it has been formed by the stretching and pushing down of the normal peritoneum in front of the descending hernia, the essential cause of the hernia in such a case being a local weakness or inadequacy of the abdominal wall. Hernia descending into an open funicular process need not of necessity find its course to the tunica vaginalis completely unopposed, but on the contrary it is common for the tunica vaginalis to be cut off from the main length of the tube by an obliterated portion of varying length. The upper portion of the partially obliterated funicular process is no whit less entitled to the name of "congenital sac" than is the whole of it, but a distinctive title of some kind was called for; and as the term "congenital" had been already appropriated by one variety, the name "funicular" was given to the other. But both are congenital and funicular in an equal degree. The author believes that we should no longer use the term "congenital" in this connection as denoting a variety of hernia distinct from all others. He suggests the use of the terms "total funicular" and "partial funicular" for those respectively now in common use, viz., "congenital" and "funicular."

British Medical Journal, March 12, 1904.

Erythema Scarlatiniforme (Influenzal).—James Hamilton calls attention to the difficulty of diagnosis in certain cases of influenza. In one case under his care sore throat developed, tenderness beneath the angle of the jaw and back of neck, and later in the day a rash appeared on the face, chest and limbs, till the patient was the color of a boiled lobster. A few months before, however, she had had an attack of scarlet fever. So the writer ruled this disease out in the present instance. He has seen a number of cases as puzzling as this one which cause the practitioner much anxiety.

The Danger of Suprarenal Treatment in Hæmoptysis.—J. Gray Duncanson describes the effect of the administration of adrenalin chloride solution in a case of hæmoptysis. The pulse became hard and there was more hemorrhage. As soon as the suprarenal treatment was abandoned, the pulse became soft and bleeding ceased. The writer feels assured that, in cases of hæmoptysis, suprarenal treatment should be withheld, unless, as he adds, the questionable procedure of spraying a solution of one of the adrenal products from an atomizer be tried as an occasional inhalation.

Reflex Disturbances Associated with Adherent Prepuce.—Robert M. Simon describes three cases. The first patient was a boy of eighteen months, who suddenly became unable to walk. He dragged one leg and complained of pain in the hip. Incipient hip mischief was suspected. Finally, the prepuce was found to be long and adherent. After circumcision the recovery was immediate and complete. The second patient was a boy of fourteen, who suffered from severe intestinal colic. Adherent prepuce was found and treated, with disappearance of all symptoms. The third child, a boy of three, began to wake up at night screaming and complaining of pain in the abdomen. The prepuce was adherent and the meatus narrow. Surgical treatment of these conditions was followed by cessation of the symptoms.

Tetany Associated with Mucomembranous Colitis and Phthisis.—H. Hyslop-Thomson presents the history of this case. The family history of the patient, a woman of twenty-one, was bad. Her father and brother had died of pulmonary tuberculosis. There were enlarged lymphatic glands close to the angle of the jaw. Percussion resonance over the front upper right lobe was diminished, while the vocal resonance and tactile fremitus were increased. Respiratory murmur was harsh and crepitations were audible. Gradually the stools became soft and slimy, while mucus and shreds of membrane, and now and then blood, were passed. There was a fairly uniform evening pyrexia. Following an attack of abdominal pain, with a discharge of blood from the rectum, there occurred a characteristic attack of tetany. The spasm was easily controlled by hypodermic injections of hyoscine hydrobromate. Heat applied to the limbs brought relief. The patient soon began to get better, and left the hospital in

an improved condition, though the physical signs were still present to a degree.

A Case of Syphilitic Convulsions Preceded by Marked Somnolence of Long Duration.—William B. Bennett gives the history of this patient, a man aged thirty-four years. One Saturday morning he awoke as usual and spoke, but when he came down to breakfast he could not utter a word, although he made great efforts to do so. About nine o'clock he fell into a comatose condition, and later had a convulsion. On Sunday morning he slept heavily, but on Monday his mind was clearer. On Tuesday he could say a few connected sentences. He was put on antisyphilitic treatment. He had felt drowsy for five months before this attack. He had never had any pain in his head or elsewhere. A history of chancre eight years before was obtained, though he had had no secondaries of any description. For some months after this attack which has been described his memory was a little defective, but this passed off completely. The writer thinks that the lesion in this case was extensive syphilitic endarteritis of the cerebral arteries, without thrombosis or embolism, but possibly with a spasm of the arteries.

Deutsche medizinische Wochenschrift, March 3, 1904.

An Antibody against Steapsin Solution.—Schütze studied the possibility of producing a serum containing antibodies having an inhibiting effect on the fat splitting property of steapsin. Rabbits were injected with 5 or 6 c.c. of this solution in intervals of three to four days until 50 or 60 c.c. had been given. Castor oil was used as test fat, and it was shown by titrating with $\frac{n}{10}$ soda solution that the steapsin solution had marked fat-splitting power. The serum obtained from the rabbits was then added, in varying amounts, to the castor oil before treating it with the steapsin, and it was found that unmistakable inhibition of the steotolysis was produced. It required from five to ten times as much serum as steapsin entirely to annul the effect of the latter. The serum was not affected in activity by heating for two hours at 55° C.

The Variability of the Gonococcus.—Schonz reiterates the view he has formerly expressed to the effect that many aberrant types of the gonococcus occur which differ widely in cultural and pathogenic properties from those usually considered typical, and that the pseudogonococci of many authors are simply variants of the typical form. This is in accord with the modification to which we have had to subject our views in the matter of the true and pseudo diphtheria bacilli, which are now generally grouped in one class. The fact that gonococci have been cultivated by Urbon and Wildbolz on ascites and glycerin-agar, bouillon, gelatin, glucose-agar, and horse serum robs the gonococcus of one of its most distinguishing features, namely, its relation to artificial media. The conclusion is that many diplococco must now be ranked with the gonococcus, including the pseudogonococci which Krukenberg isolated from the conjunctiva. The question as to the identity of the meningococcus intracellularis will probably a so be settled by including it in the gonococcus group.

The Value of Jousset's Inoscopy.—Kormoczi and Jossniger have repeated Jousset's procedure for detecting tubercle bacilli in blood and exudates. The method consists in collecting small quantities of the suspected fluid in sterile glasses and allowing it to stand till the separation of flocculi of fibrin has taken place. The sediment is strained off, is washed with water and then digested in the incubator with a solution containing pepsin, glycerin, hydrochloric acid, sodium fluoride, and distilled water. The digested mass is centrifugalized and smears are made from the deposit and stained by Gaffet's method. Blood is diluted with distilled water before coagulation. Jousset obtained remarkable results in this way, and found the tubercle bacillus in seventeen cases of pleurisy in supposedly non-tuberculous patients. It was present in eight out of twelve cases of doubtful ascites, and was found in the blood of two cases supposed to be typhoid fever. The authors repeated Jousset's work with great care, using autopsy material in order to have an absolute check on the diagnosis. The number of positive results was much smaller than expected, the method failing even on well-marked tuberculosis cases, so that the conclusion is that though a useful method which often gives positive results, in much less time than they could otherwise be obtained, the negative findings are not certain evidence of the non-existence of a tuberculous process.

Münchener medizinische Wochenschrift, March 1, 1904.

Atropine in Mechanical Ileus.—Boseck adds another to the list of cases in which obstruction has been relieved by atropine in large doses. The patient was a man of forty-two years with recurrent carcinoma of the mesentery, who on two occasions after periods of mechanical obstructi lasting ten and eight days respectively was relieved by t hypodermatic injection of four milligrams of the dr He succumbed to a third attack in spite of a similar inj tion. The author recommends the measure as one to tried when the diagnosis is doubtful for operation refused.

The Mucous Membrane Eruption of Measles.—Ri reports observations on 520 cases of measles occurring a recent epidemic in Erlangen. On the whole, the res are in accord with the statements of Koplik and corro rate the value of his sign as an aid to early diagnosis. a number of cases the author observed as earliest sy toms, even before the buccal enanthem, subjective ph phobia and congestion of the conjunctiva of the lower The description of the eruption as seen does not di notably from the classical one, but the author found t the bluish or yellowish point forming the center of the could easily be brushed off without causing bleedin some authors aver, and that it was composed princip of desquamated epithelial cells with poorly staining nu He regards the red spots as the true enanthem and white epithelial desquamations merely as more or less stant indications facilitating the recognition of the m læ. Owing to the congestion and swelling of the ly atic follicles of the soft palate accompanying most dis of the mouth, this region is a less favorable one in w to endeavor to identify the spots of measles. In no the other infectious diseases examined, such as rub diphtheria, follicular and suppurative angina, were spots found. Out of 3,972 cases of measles occurri Erlangen since 1859, the maximum number came in with smaller increases in late March and early April in late October and early November.

Egypt and Tuberculosis.—V. Becker, who has twenty-two years in different parts of the country cusses the suitability of Egypt as a resort for cons tives. Many recent writers have recommended it f dryness of its atmosphere, but the author does not it as an altogether satisfactory place of residence fo patients. Certain races of natives, particularly th lahs and Bedouins, exhibit but little tendency to tu losis and the disease is rarely seen among them, but o like the Copts, and particularly the Nubians fro southern cataract regions, show a marked predispo for it. All races of negroes fall easy prey to tuberc and exhibit the same susceptibility that imported mo do. The advantages the climate offers are those humidity and of transferring much of the work lungs to the large glands and the skin. This ent increase in the work of the heart, and cardiac inc tence frequently develops in white colonists. The of tuberculosis most favorably influenced is that hypersecretion and large amounts of expectoratio these the improvement is often most surprising e cavities exist, but laryngeal cases do particularly The summer is rendered very uncomfortable for a cigners and decidedly injurious for the sick by the *cha* a hot, exceedingly dry wind loaded with sand, and few patients can stand it. The cost of living is also double of that in Germany.

Berliner klinische Wochenschrift, February 29, 19

The Osmotic Pressure of Exudates and Transuda Rzentkowski determined the freezing points of a ser these fluids, but finds that the differences they exhib too slight to permit of their being of great diag value. In general it may be said that the freezing po an exudate is lower the greater the number of pus it contains, and that tuberculous exudates, regardl their origin, have the smallest molecular concentr The concentration rises in rheumatic exudates, a greatest in purulent fluids, in which it increases with age. The molecular concentration of exudates is pendent of the composition of the blood, but the centration of transudates is higher and depends o nature of the primary chemical disturbance of the b

The Effect of the Galvanic Current on Tetanus T Antitoxin, and Mixtures of the Two.—Römer says observations with the ultra microscope of Sieden Zsigmondy show that the toxic properties of bac poisons are combined, not with genuine albumins with albumoses or nearly allied bodies. Such albumo pepton molecules are much smaller than those of ge albumins but are still to be regarded as forming col solutions. As substances in this condition when jected to electrical currents exhibit activities simil those of ions but without dissociation of the molecul author undertook some investigations on the effect galvanic current on tetanus toxins and antitoxins. fluids were placed in U-shaped tubes having the anod one and the cathode in the other arm of the tube. After

rrent had been passed, the anodal, cathodal and inter-diate portions of fluid were separately pipetted off d their toxicity tested. The results showed that weak rents increased the toxic action of the fluid both at the de and cathode and to some extent in the total fluid, that it seems possible to reactivate, to some extent, toxin t has lost virulence. Strong currents (over 2 ampères) inish the toxicity both at the anode and in the mixed ds, while at the cathode the toxicity is reduced to a less ee or even raised. Even the short passage of relatively k currents sufficed to produce a uniformly distributed inution in the antitoxic power of tetanus antitoxin. ompletely inactivated mixtures of toxin and antitoxin n subjected to the current showed the unexpected lt of a rapid diminution in virulence and soon became rely inactive. In a closing paragraph v. Behring phasizes the importance of these observations, and mises further communications from his laboratory on subject and on that of the antibacterial substances in .

e Bactericidal Action of Typhoid Blood Serum.—Stern Korte report on some interesting observations made letermine the bactericidal potency of the serum of hoid patients. The technique was as follows. The hoid serum in the requisite dilution is added to a half of a 1-5,000, twenty-four-hour froth culture of hoid bacilli, together with a diluted rabbit serum to ide the complement. In less dilute strengths of the an serum a preliminary heating to 55° is necessary, with the weak solutions this may be omitted. ether with suitable controls, a series of tubes con-ng different amounts of the typhoid serum is placed e incubator and allowed to stand for three to four s. The contents of the tube are then poured on r plates and the proportions of the colonies developing the different tubes noted after twelve hours. All the examined from patients still in the febrile stage, or tly after it, showed marked bactericidal action in ions of over 1-1,000, and in most cases the effect was eptible in a dilution of 1-50,000,and in some even in veral millions. None of the cases were examined r than the eighth day. One case just before a severe se showed bactericidal action in a dilution of one to million, a fact having an interesting bearing on the tions of immunity and serum therapy. In all cases bactericidal strength was much greater than the utinating strength, often being one hundred or more s as strong, but no relationship between the activity e two could be established. The serum of five patients had had typhoid fever several years previously showed tronger bactericidal action than is often observed in non-hoid cases. The diagnostic value of the reaction can stated only by saying that the greater the dilution hich it occurs the greater its diagnostic significance, as is the case with the agglutination reaction. For ctical use it will be found serviceable in cases in which agglutination reaction is absent or is doubtful, as it is erior to it in sensitiveness.

French and Italian Journals.

adiotherapy in Cancer.—Oudin reports certain obser-ions proving that when tumors. sarcomata or epitheli-ata are treated by the *x*-rays, there are sometimes pro-ed general phenomena, it may be of miliary generali-on, or it may be of intoxication, due probably to the that morbid products from the cancerous focus are own in great abundance into the circulation from ence they are absorbed. The symptoms consist of exia, diarrhœa, vomiting, general depression, and ed death may be the outcome. It is necessary, then, such cases to proceed with caution in order that the anism may be able to eliminate all waste matter. e must be taken that the power of resistance of the dy shall not be overcome by the absorption of the mulation of toxins.—*Le Bulletin Médical*, March 9 04.

Case of Tetanus Cured.—Potherat reports the case of a ng boy of sixteen years, who, eight days after being nded in the hand by a piece of iron, was seized with symptoms of tetanus. The patient was carried to the pital and received an injection of 10 c.cm. of antitet-ic serum. This treatment met with no result. Poth-t determined to return to the old method of treating disease with large doses of chloral. The wound was t carefully cleansed. The patient was isolated, and jected to the treatment by chloral. The dose was car-d up to thirty grams a day. On the third day the mptoms began to grow less. The treatment was con-ued, nevertheless, for thirty days with doses of chloral rying from ten to fifteen grams, and now seven weeks er the accident the patient is completely cured.—*La esse Médicale*, March 2, 1904.

Metrorrhagia and Ovarian Cysts.—E. Camelot declares that metrorrhagia is far from being frequent in the course of the evolution of ovarian cysts. However, these cases cannot be called exceptional. Out of 169 cases that he has studied from the point of view of the influence of these neoplasms on menstruation, Gaillard has noted that in about one-fifth of the cases menstruation was suppressed or diminished in quantity, or retarded; in one-eighth of the cases it was augmented in quantity or in duration; in a certain number it had become irregular or painful. It was noted that ovarian cysts caused amenorrhœa rather than metrorrhagia. But there was nothing of much significance in these observations. The writer reports two cases. The first patient was a girl of eighteen years who suffered from severe hemorrhages. No lesion could be found either in the uterus or in its appendages. Under ether, however, the cyst was demonstrable. After its removal, normal menstruation soon returned. The second patient was a woman forty-eight years of age. After the removal of the cysts, the hemorrhages immediately ceased. —*Journal des Sciences Médicales de Lille*, March 5, 1904.

Movable Heart and Cardioptosis.—E. Barié says that in the treatment of this condition the most important thing is to mitigate the nervous symptoms, and, secondly, to try to combat the mechanical difficulties. For the nervous disturbances one should use hydrotherapy, bathing, cool sponging, gas baths, and out-of-door life. Bromides and valerianates in small quantities are very useful and suggestion should be pushed to the psychical limit. Treatment of the displacement consists in avoiding the assumption of certain predisposing positions, and at night the head must be kept low. A pad may be worn to give the left side support and help keep the heart up. A cardiac belt, made with a concave metal plate or a corset, is very useful. The etiology of this condition probably depends on the relaxation and want of resiliency in the great vessels. These, however, become less flabby with age, which accounts for the greater frequency of the trouble in the young. This condition may be dependent on a congenital deficiency in the elastic tissues of the vessels. This lack of elasticity is shown in pernicious anæmia. Prognosis in these cases is never more serious than that of an asthenia caused by the nervous symptoms. Perhaps this condition may lead to cardiac dilatation. The cardiac displacement must be distinguished from bathycardia or low heart.—*La Presse Médicale*, January 27, 1904.

Carcinoma of the Sudoriferous Glands.—Gustavo Lusena gives an excellent résumé of the subject of growths of the sudoriferous glands. Carcinoma of these glands is exceedingly rare, only a few undoubted cases having been published, to which he adds one of his own. Adenoma and epithelioma involving these glands are both more common, and most of the published cases are of this nature. In the true hypertrophy of these glands, whether physiological or pathological, the location of the growth is at the point of greatest activity of the normal glands. Lusena's case occurred in a patient at the age of sixty-three, beginning in the right gluteal region, near the anal fissure, and increasing in five months from its beginning to the size of an egg, ulcerated in the center, where it had been incised. The tumor was not at all painful, and gave inconvenience only in sitting and walking. It was at once removed, but recurred in five months in the scar. The new tumor was removed, and at the time of the report, four months later, had not recurred for the second time. The tumor originated in the deepest parts of the corium and the subdermal tissues. It consisted of larger or smaller tubes, and cystic cavities containing amorphous material with cellular elements intermixed. There seemed to be no doubt of the origin of the tumor, which by its atypical formation, the active proliferation of the typical epithelium, the lack of a limiting membrane, its rapid growth and recurrence, seemed to be an adenocarcinoma of the sudoriferous glands. It showed a gradual transition in different parts of its structure from the normal glands to the atypical tumor formation. Lusena thinks we should distinguish between two types of sudoriferous carcinomata the single and the multiple. In the first we have a single tumor, rapid in its development, without pain, encroaching on the surface of the skin, relatively soft, not infiltrating the neighboring lymphatic glands, having a possibility of recurrence and a relative benignancy. Its histological characteristics are the formations of tubules or cysts lined with cylindrical epithelium, in a state of active proliferation. The second form is multiple, the nodules tending to run together and form plaques, of rapid diffusion, and forming new nodules quickly; pain is more marked, and the lymphatic glands are involved. Under the microscope there are solid tubes and masses of cuboidal epithelium, which infiltrate the connective tissue in all directions, forming a true carcinoma.—*Lo Sperimentale*, February, 1904.

Book Reviews.

ORGANES GÉNITO-URINAIRES DE L'HOMME. Par HENRI HARTMANN, Sous-directeur des travaux pratiques de Médecine Opératoire à la Faculté de Médecine. Paris: G. Steinheil, 1904.

THIS is a collection of lectures given by the author in 1902, amplified and extended, illustrated and elaborated, until we have before us a rather complete treatise of 432 pages. While minor operations receive brief mention, the important and complicated ones are described with full detail, and the illustrations are often made with the patient in the position for operation, thus presenting the relation of anatomical parts more as the operator sees them than when the drawing is made in the vertical position. The work may be taken as an accurate guide to the diagnosis and surgical treatment of genitourinary diseases in man as this branch is taught to-day in France.

THE EYE, ITS REFRACTION AND DISEASES. The Refraction and Functional Testing of the Eye Complete in Itself, in Twenty-eight Chapters, with Numerous Explanatory Cuts and Diagrams. By EDWARD E. GIBBONS, M.D., Assistant Surgeon of the Presbyterian Eye, Ear, and Throat Hospital; Demonstrator and Chief of Clinic of Eye and Ear Diseases in the University of Maryland, Baltimore. New York: The Macmillan Company, 1904.

THE volume is one of 472 pages, is admirably printed and beautifully and fully illustrated. The title of the book is somewhat misleading in that the diseases of the eye are considered only in their relation to the optics of the eye and the mechanism of motility. It is really a work on physiological optics, the subject being introduced by chapters on light, its propagation and refraction, the properties of prisms and lenses, and the phenomena of reflection. The principles which govern these phenomena are explained in a direct and sufficiently elaborate manner, and the appropriate formula are given. A chapter is devoted to the gross anatomy and to the physiology of the eye, and this is followed by some twenty-four chapters on the various phases of physiological optics. The author shows himself to have a masterful grasp of the subject, and presents it clear "and concise." The directions given for determining the state of the refraction of the eye and the condition of the muscles, for the proper adjustment of glasses, the acuity of vision, the extent of the fields of vision, and the color sense are complete and reliable.

The work is an admirable one and is worthy of careful perusal by all who are interested in ophthalmology or in physiological optics. It occupies a plane below that of Donders and Landolt, so far as pure physiological optics is concerned. In regard to the methods of determining and dealing with the refraction and motility of the eye, it is superior to older works, as it is thoroughly up to date.

PHYSIOLOGISCHE UND KLINISCHE UNTERSUCHUNGEN ÜBER DAS GEHIRN, GESAMMELTE ABHANDLUNGEN. Von Dr. EDWARD HITZIG. Berlin: A. Hirschwald, 1904.

THE book, as the title tells us, is a complete collection of Hitzig's publications on his experimental work of localization of function to the cerebral cortex. The volume is divided into two parts, the first of which is an enlarged edition of his earlier works. The second part, entitled "older and later" studies of the cerebrum, is very complete, and comprises a critical review of the different theories concerning the function of the brain, together with his own observations.

A chapter is devoted to a close criticism of Ferrier's work, and in this the latter's conclusions are attached very sharply. The author says in résumé: "Ferrier, by means of a method exposed to every sort of criticism, and in a very superficial manner, has established that strong electrical currents for the anterior and basal region of a dog's brain produce chewing movements. That constitutes his share of praise. On the other hand, he has not found once with any degree of certainty the focal points which we have established; he has published a mass of observations concerning focal symptoms which can be explained by inconstant or faulty methods; and finally he has fitted this work without nomenclature, with discoveries which do not belong to him but to us."

In chapter III of the second part, the theory of cortical inhibition and subcortical centers for the coarser movements, as propounded by Goltz, Loeb, Bubnoff, Heidenheim, and others is discussed very freely, and the author, relying on his own experiments, does not concur in their opinions. In reviewing Munk's work we find that he really differs very little from that author, principally in nomenclature. Altogether, it is one of the most valuable and important contributions to the study of brain functions that we possess at present; one to which the student of neurology must go and one to which the historian of medicine will go gladly.

DAS EINDRINGEN DER TUBERKULOSE UND IHRE RATIONELLE BEKÄMPFUNG. Nebst kritischen Bemerkungen zu E. v. Behring's Tuberkulosebekämpfung. Von Dr. HUGO BECKMANN. Berlin: S. Karger, 1904.

IT is the author's opinion that tuberculous infection occurs mostly during childhood, and that it is the pharyngeal tonsil which forms the portal of entry for the organisms. From here they enter the lymphatic stream, and after passing the cervical nodes may reach the bronchial glands and either remain quiescent or cause metastases in the lungs or elsewhere. The prophylaxis of tuberculosis therefore consists in surgical treatment of the nasopharynx, nose, and pharynx.

DIE ERRICHTUNG GEBURTSHÜLFLICHER POLIKLINIKEN AN HEBAMMENSCHULEN; ihre Bedeutung für die Ausbildung der Hebammen und für die allgemeine Hygiene. Von Dr. FRITZ FRANK, Direktor der Prov. Hebammenlehranstalt in Köln. Berlin: S. Karger, 1904.

THIS brochure is an argument in favor of the policlinical training of midwives, and describes the essential features of the course given in the author's institute in Cologne. Although the outdoor department at first encountered much opposition, its value was speedily recognized, and it has now become very popular.

MODERNE ÄRZTLICHE BIBLIOTHEK. Herausgegeben von Dr. F. KAREWSKI, Berlin. Heft 1. DIE WISSENSCHAFTLICHEN GRUNDLAGEN DER KRYOSKOPIE. Von Prof. Dr. A. VON KORANGI. Berlin: Leonhard Simion, 1904.

THE object of this series of essays is to provide authoritative résumés by specialists of the progress that is being made in theoretical and applied medicine. Each pamphlet will contain a paper on a single subject, treated in a strictly scientific but easily comprehensible manner. The first number, on cryoscopy, augurs well for the usefulness and success of the series.

LA TORSION DU CORDON SPERMATIQUE ET L'INFARCTUS HÉMORRHAGIQUE DU TESTICULE. Par le Dr. ANDRÉ LAPOINTE, Ancien Interne Lauréat des Hôpitaux de Paris, Ancien Aide d'Anatomie à la Faculté, Lauréat de l'Académie de Médecine. Paris: A. Maloine, 1904.

THIS little work, devoted to a pathological condition which has hitherto been rarely dignified by a monograph, may be said to "fit a space." There is opportunity for fine points in differential diagnosis, especially when we have to do with a testis in the scrotum. The 180 pages, including bibliography, may be read with advantage by any practitioner.

SEHPROBEN-TAFELN; mit besonderer Berücksichtigung des militärärztlichen Gebrauchs. Von Dr. BERTHOLD KERN und Dr. REINHOLD SCHOLZ. Berlin: August Hirschwald, 1904.

THE test-cards are designed for determining the acuity of vision only. Six cards with characters in black on white ground are supplied. The characters are letters and figures of the ordinary block type, constructed, after the principle laid down by Snellen. Two of the cards have the characters arranged in the ordinary manner. Three cards, one of which is arranged to read by reflection from a mirror, have large and small characters intermixed and arranged in broken lines and diagonally. One card is for testing near vision and is in German. There is nothing to commend this arrangement over that in general use, except perhaps it may be a little greater approach to accuracy in the construction of the letters.

TRAITÉ D'HÉMATOLOGIE. Par FERNAND BEZANÇON, Professeur Agrégé a la Faculté de Médecine, Médecin des Hôpitaux, et MARCEL LABBÉ Chef de Laboratoire à la Faculté, Médecin des Hôpitaux. Avec 125 Figures et 9 Planches en couleurs, d'aprés les Aquarelles de M. Labbé. Paris: G. Steinheil, 1904.

THIS is the most pretentious treatise on the blood which has yet appeared in the French language. The book is divided into seven sections, and in these the subject is treated under the following captions: (1) The Physics, Chemistry, and Bacteriology of the Blood in Its Entirety. (2) The Enumeration and Mensuration of the Red and White-blood Cells. (3) The Red-blood Cell. (4) The leucocyte. (5) Hæmatoblasts. (6) The Serum. (7) The Blood-forming Organs. In these sections the histology, pathology, and technique of the subjects considered are given side by side. The histological and pathological portions are especially voluminous, and consist essentially of a recital of the work of various observers with respect to these themes. As a bibliographical collection, therefore, the work must be rated high, since it will be found that practically all of the work the world over which has been done in these directions receives mention. It is to be regretted that, as a rule, the authors have refrained from personal comment upon the themes treated, so that the reader, unless he be a special worker in hæmatology,

will be at a loss to comprehend the actual status of the subjects considered. The technical portion of the book cannot be commended, as it is incomplete. This is especially true with respect to staining the blood for the malarial organism and the differentiation of leucocytes. In the sections devoted thereto, Jenner's and Wright's stains (two of the best) receive no mention. It will hence be clear that as a work of histological and pathological reference it possesses value for the specialist in hæmatology, but that as a general textbook upon the subject it is not likely to attain a high rank.

A Laboratory Manual of Physiological and Pathological Chemistry. For Students in Medicine. By Dr. E. Salkowski, Professor in the University and Director of the Chemical Laboratory of the Pathological Institute, Berlin. Authorized Translation from the Second Revised and Enlarged German Edition. By W. R. Orndorff, A.B., Ph.D., Professor of Organic and Physiological Chemistry in Cornell University. With Ten Figures and a Colored Plate of Absorption Spectra. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1904.

This first English translation of Salkowski's "Practicum der physiologischen und pathologischen Chemie" corresponds to the second German edition of that work, with the exception that the sections on inorganic chemistry are omitted. In addition to giving the tests for carbohydrates, fats, and proteids, the examination of milk, muscular tissue, adipose tissue, bone, pathological transudates, bile, biliary, and urinary calculi, blood, and urine is taken up in considerable detail. A section on quantitative analysis concludes the book. The technical descripton of the tests is eminently satisfactory, in that the minutest details are clearly stated, so that the beginner can make no mistake regarding their proper execution. The preparation of the various testing reagents used is accurately given. This latter is an exceedingly praiseworthy feature of the work, as it is usually omitted in manuals of this character. As a laboratory aid to the beginner, the book deserves the highest possible praise.

Electrodiagnosis: Scheme for the Differential Testing of Nerves and Muscles, for Use in Diagnosis. By J. Montgomery Mosher, A.M., M.D., Clinical Professor of Insanity, Neurology, and Electro-therapeutics, Albany Medical College; Attending Specialist in Mental Diseases and Physician to the Out-patient Department for Nervous and Mental Diseases, Albany Hospital. Illustrated. Albany, N. Y.: Brandow Printing Company, Fort Orange Press, 1903.

In this little book of fifty-eight large octavo pages very much is compressed. There is hardly a waste word, and the keynote of the whole treatise is terseness and condensation, and practicality. These tables have, the author tells us, been prepared for the purpose of facilitating electrodiagnosis. They are the result of repeated examinations at the Albany Hospital, which have shown the great advantages of precise anatomical localization over the time-honored charts of von Ziemssen. No other publication has been issued in which the nerve and muscle groups have been classified for this purpose, and no attempt at such description exists in English. The scope of the work may be judged from the principal section headings, namely, the technique of electrodiagnosis; quantitative and qualitative variations in electrical excitability, the mild, medium, and severe degrees and atypical forms of the reaction of degeneration; the myotonic, myasthenic, myoclonic, and neurotonic reactions; electric sensibility; electric resistance, and the motor points. Altogether this work forms an exceedingly convenient reference book.

Social Diseases and Marriage; Social Prophylaxis. By Prince A. Morrow, A.M., M.D., Emeritus Professor of Genitourinary Diseases in the University and Bellevue Hospital Medical College, New York; Surgeon to the City Hospital; Consulting Dermatologist to St. Vincent's Hospital, etc. New York and Philadelphia: Lea Brothers & Co., 1904.

No one will question for a moment the great importance of sexual diseases, as they influence society. Whether all will agree that they should be called social diseases is questionable, so much syphilis being acquired in non-sexual and non-social ways. The relation of gonorrhœa and syphilis to the marriage state cannot be too carefully studied from the side of prophylaxis. It was over twenty years ago the present author appeared as the translator of Fournier's classic work upon this subject, and his interest in the question has been shown in numerous writings since. The present volume, though modeled somewhat after that of Fournier, presents the present-day thought upon these matters, and presents it in a fluent, pleasing style. The work will undoubtedly be largely read by those outside the profession, and whether or not this is the author's expectation, in lay hands much good might be accomplished. There are no illustrations, and few bibliographical references. The chief feature may be said to be the rule of action to be followed by the physician when confronted with the numerous and at times complicated problems connected with the marriage contract when one of the contracting parties may transmit disease to the other, or to offspring. The publishers have done their part in presenting an attractive volume.

A Handbook of Ophthalmic Science and Practice. By Henry E. Juler, F.R.C.S., Ophthalmic Surgeon to St. Mary's Hospital; Consulting Surgeon to the Royal Westminster Ophthalmic Hospital; Consulting Ophthalmic Surgeon to the London Lock Hospitals. With Illustrations. Third Edition. Revised and enlarged. Philadelphia: Lea Brothers & Co., 1904.

Some eleven years have elapsed since the second edition of the author's work appeared, and in this, the third edition, there has been ample opportunity given to add the changes made in ophthalmology during that time. Several hundred pages have been added, and the chapters on The Eyelids, Conjunctiva, Cornea, Uveal Tract, and Optic Nerve and Retina, have practically been rewritten, especial attention to pathology and tumors involving the various structures being given. Injuries of the eye and its parts are considered in a separate chapter. Considerable space is given to illustrating Worth's instruments and to describing his operation for strabismus, which the author strongly advocates. Under the table of contents the term scleritis is happily substituted for sclerotitis. A glossary has been added, and the index is more comprehensive than in the previous editions. The appendix on "Formulæ" is conservatively enlarged, while that on "Testing Vision for Service of Army and Navy Applicants" is added. Still another appendix of half-tone plates, illustrating "The Normal and Pathological Histology of the Eye," is given.

Studies in Heterogenesis. By H. Charlton Bastian, M.A., M.D., London, F.R.S., Fellow of the Royal College of Physicians of London, Hon. Fellow of the Royal College of Physicians of Ireland, Hon. M.D. Royal University of Ireland; Corresponding Member of the Royal Academy of Medicine of Turin, and of the Medicochirurgical Society of Bologna; Emeritus Professor of the Principles and Practice of Medicine and of Clinical Medicine in the University College, London; Consulting Physician to University College Hospital, and to the National Hospital for the Paralyzed and Epileptic. With 815 illustrations from photographs. London: Williams & Norgate, 1903.

This work is a collection of the studies of the author with respect to the heterogenetic origin of lower organisms. It consists of a detailed description of numerous experiments along these lines, together with argumentation relative to their import. The book is divided into four parts, which include twenty-six chapters. Beginning with the transformation of the contents of confervoid and other vegetal cells and organisms into amœbæ, actinophrys, monads, peranemata or monad cysts, the subject is followed in logical order up to the origin of bacteria and their allies by heterogenesis. For several years the views of the author, who believes in the de novo origin of microorganisms and the transmission of one species into another, have been well known. They have never received recognition. To consider here in detail the facts which controvert the author's opinions, would encroach upon the reader's patience, but in general it may be said that the day is past when the *de novo* origin of microorganisms deserves serious consideration at the hands of competent workers. It does not seem as though the present volume was likely to further the acceptance of the author's views, since its essential purport is not other than has previously emanated from the same quarter. However this may be, in many respects the book forms interesting reading for those who are at work in biology, whether or not they are able to concur in the sentiments expressed.

The Treatment of Neurasthenia. By A. Proust, M.D., Professeur à la Faculté de Médecine de Paris, and Gilbert Ballet, M.D., Professeur agrégé à la Faculté de Médecine de Paris. Translated by Peter Campbell Smith. L.R.C.P., L.R.C.S., Edinburgh; L.F.P.S., Glasgow. New York: Edward I Pelton, 1903.

This little book presents a graphic and concise exposition of our present knowledge of neurasthenia. The subject is treated in a thoroughly practical manner indicating broad experience and precision or observation on the part of the authors. The classification of the various clinical types of neurasthenia, and the details in the treatment are vividly and lucidly explained.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 25, 1904.

A. DUDLEY PALMER, M.D., CHAIRMAN.

Fibromata of the Uterus.—Dr. HERMANN J. BOLDT presented several specimens of this nature. The first was one of myofibroma uteri with cystic degeneration, in a woman of thirty-six years. The growth was removed by abdominal hysterectomy, but the patient died in thirty-four hours, apparently from secondary shock.

The second specimen was one of a very large tumor, which had filled the pelvis, giving rise to obstinate constipation from pressure on the rectum, and to excruciating pain in the pelvis, back, and thighs. Because of her suffering the woman had become a morphine *habitue*. Beginning on the third day after the operation, her daily allowance of morphine was gradually reduced, and stopped entirely on the twelfth day. She was now free from all the symptoms which the tumor had caused and had no further desire for narcotics.

The third specimen was one of myofibromatous uterus removed by vaginal hysterectomy. The diseased uterus in this case had given rise to menorrhagia, and intense bearing-down pain during the intervals of menstruation. The patient was a woman forty-eight years old. The growths in this case were so small that under ordinary circumstances one would not expect them to cause sufficiently severe symptoms to require medical advice, much less a radical surgical operation.

A fourth specimen was one of submucous myoma, removed by abdominal hysterectomy from a patient who had been normally delivered four months previously.

Large Ovarian Cystoma.—Dr. BOLDT presented another specimen which he had removed from a woman fifty-four years old. The tumor had been present for several years. Three months ago she experienced a sharp pain in her abdomen; this increased in intensity and a physician was sent for who ordered flaxseed-meal poultices. She remained in bed for nearly four weeks, and since then had been up only part of the time. The abdomen was sensitive to pressure, and the patient suffered from obstinate constipation. The temperature varied from 101° to 102.5° F. A diagnosis of ovarian tumor with a twisted pedicle was made, and confirmed on operation. After the extensive adhesions attaching the tumor to the parietal peritoneum had been separated, it was seen that the pedicle had partly sloughed off. The walls of the tumor were very friable, making the enucleation of the growth tedious. The only reason to account for a non-fatal termination from septic peritonitis was that seemingly the collateral circulation between the adhesions of the tumor and the peritoneum sufficed to prevent complete gangrene of the sac wall. The patient developed bronchopneumonia on the second day after the operation, but eventually made a good recovery.

Supravaginal Hysterectomy for Fibroids in a Pregnant Uterus.—Dr. HIRAM N. VINEBERG showed this specimen, which he said was a good illustration of the fact that pregnancy at times occurred under the most unfavorable conditions. The patient was a woman, thirty-four years old, who had been married seven months when he first saw her, and was then between two and one-half and three months pregnant. She complained of some hemorrhage for the past two or three days, and considerable pain. Upon examination, he made out a large uterus, with a growth which was located largely in the cervix. It was impossible to introduce any dilating instrument into the cervix. The patient had some symptoms of sepsis, with a temperature of 101 and a pulse of 110. A supravaginal hysterectomy was done and the patient made an uneventful recovery.

A Case of Transposition of the Heart and Abdominal Aorta.—The Chairman, Dr. A. PALMER DUDLEY, exhibited an overgrown girl of nineteen years who was operated on by him for catarrhal appendicitis. An examination of the patient previous to the operation revealed the fact that the heart was located to the right of the sternum. In the course of the operation for the removal of the appendix, the speaker said he took the opportunity to trace the course of the abdominal aorta and found that it descended to the right side of the vertebral column, and bifurcated on that side. A pelvic examination revealed an infantile uterus and ovaries.

Bilateral Papillo-carcinomata of the Ovaries, with Metastases.—Dr. CHARLES H. PECK presented this patient and showed the specimen removed. The patient was a widow, forty-eight years old, who was admitted to the French Hospital on January 9, 1904. About a year ago she began to suffer from pain in her back and legs after long standing. Subsequently she had anorexia, and last summer she was troubled with diarrhœa and swelling of the abdomen, the latter symptom developing gradually. Since September the swelling of the abdomen had increased more rapidly and was accompanied by swelling of the feet. About two weeks previous to her admission the abdomen was so tense that tapping was resorted to and several quarts of fluid withdrawn. Temporary relief followed, but the fluid soon re-accumulated. Examination showed the abdomen distended with fluid. By vaginal examination a mass could be felt to the left of the uterus, but its outlines were not distinct. There was a soft, blowing systolic heart murmur; pulmonary sounds were normal; the urine showed no evidence of a kidney lesion. The patient was somewhat emaciated; otherwise her condition was fair. The possibility of cirrhosis of the liver, with ascites, was considered, but the presence of the pelvic mass led Dr. Peck to advise an exploratory incision. The operation was done on January 12. A short median incision was made below the umbilicus: through this several quarts of clear fluid were evacuated and the presence of large papillomatous masses in the pelvis demonstrated. Two large papillomatous masses, which bled freely on manipulation, filled the pelvis on each side. There were many metastatic deposits on the omentum, one of which was firmly adherent to a loop of small intestine. The entire omentum lay to the right of the median line, adherent in many places to coils of small intestine and below to the pelvic organs and parietes. It was ligated, separated from its adhesions, divided just below the transverse colon and excised. Each papillomatous mass was then excised with the corresponding ovary and tube. There were many small nodules on the parietal peritoneum which could not be wholly removed: small nodules were also left in the stump of the omentum. The main tumor masses were large, cauliflower-like growths, friable, and very vascular. The patient made an uneventful recovery from the operation. A pathological examination of the growths was made by Dr. James Ewing, who reported that they were adenocarcinomata.

Sterility.—This was the subject of discussion announced for the evening.

Sterility Due to the Male.—Dr. EGBERT H. GRANDIN, in this paper, emphasized the importance of gonorrhœa and syphilis as etiological factors in the production of sterility and entered a vigorous protest against present educational methods by which young men were kept in ignorance of the widespread dangers attending the contraction of these diseases. Gonorrhœa was responsible not alone for sterility, but also for many cases of pelvic disease in women and blindness in children. Man was responsible for race suicide in its true sense: in fully 45 per cent. of the cases of sterility in women, the man was the responsible party. With syphilis, while a woman might conceive, she as a rule miscarried, which practically amounted to sterility. The laity failed to realize and physicians did not lay suffi-

cient stress on the preponderant influence of the rôle played by men in the etiology of sterility in women. In every case of sterility, the semen of the male should be examined, because, although a man might be able to copulate, he might be incapable of impregnation. In from 5 to 8 per cent., sterility was due to the fact that the man was sterile, in that his semen did not contain spermatozoa, although he possessed the power to perform the sexual act. Every young man should be instructed as to the risk he ran when he contracted gonorrhœa or syphilis, and the possible risk he carried to the woman whom he married. By proper educational methods, the operating gynecologist would be deprived of nearly 60 per cent. of his work, while on the other hand the human race would be immeasurably benefited. In concluding his paper, Dr. Grandin said that from the present standpoint, man was not the boasted lord of creation, but the exterminator of his species, and of all the animal creation, he showed the least regard for his mate, in that he often implanted into her system a disease which rendered her sterile.

Sterility from Vaginal Causes.—Dr. JAMES N. WEST said that a division of sterility in women into causes due to derangement of any particular parts of the system of generation was to a certain extent arbitrary and impossible, since such derangements graded insensibly from one part to another. Still, a study of the subject in this way had its advantages, in that it concentrated the attention upon details which might otherwise be lightly considered. The part which the vagina took in the physiology of reproduction was that of the chief organ of copulation in the female: its function was to produce the ejaculation of semen from the male and retain it in a healthy condition in such proximity to the cervix that it might readily find access to its canal. The causes that interfered with its function were congenital, pathological, traumatic, and psychical. Congenital causes: Among the congenital causes the reader discussed pseudo-hermaphroditism; congenital absence of the vagina; vaginal septa and bands and double vagina; congenital atresia; unusual changes due to congenital malformations; persistent hymen and imperforate hymen. Pathological causes: These the author considered the most frequent and necessarily the most important causes of sterility due to the vagina. Among them he mentioned new growths; carcinoma of the cervix; sarcoma; vaginal cysts; fibroids in the uterus or cervix occupying the vagina; syphilitic growths; inflammatory conditions resulting in abnormal secretions inimical to the life of spermatozoa. Traumatic causes: Among these he considered vesicovaginal fistula as one of the most striking. Complete procidentia was usually accompanied by sterility, but destruction of the hymeneum or the presence of a cystocele or rectocele seemed to have little influence in that direction. Atresia of the vagina due to the disease or trauma might act as a bar to normal insemination; the same was true of vaginismus, due to injury or disease. Psychological causes: The writer said it had been fairly demonstrated in a limited number of cases by good observers that incompatibility was a cause of sterility. Under this heading might also be included many cases of vaginismus in which the distaste for the sexual act produced a reflex contraction of the sphincter muscles of the vagina of such violence as to prove an effectual bar to copulation. In the treatment of congenital malformations of the vagina when the other organs were normal, Dr. West thought we were justified in resorting to any reasonable surgical measure for correcting it. The treatment of pathological conditions was suggested by the nature of the cause. In the case of new growths they should be removed, but when of malignant character, conception should be guarded against. When the sterility was due to an excessive and acrid secretion of acid mucus, it might be relieved by the judicious use of antiseptics and local applications, among which the very best was nitrate of silver. Local applications of alcohol sometimes seemed to have a very beneficial effect. The relief of sterility due to traumatic causes offered a wide field of usefulness, and operations for the relief of procidentia, cystocele, rectocele, lacerations, and vesicovaginal fistula at once suggested themselves. When the sterility was really due to psychological causes the physician could offer practically no relief. Finally, each case should be carefully considered on its own merits, its etiology thoroughly established, and a definite plan of treatment mapped out and persisted in until relief was obtained.

Sterility Due to Abnormal Conditions of the Uterus.—Dr. HIRAM N. VINEBERG said that sterility due to the uterus must be classified as primary and secondary. The first was that form in which the patient had never conceived. Secondary sterility was that form in which the patient had borne one or more children, but the last pregnancy and consequent delivery or other processes had induced such changes in the uterus that the woman was unable to conceive subsequently. The most frequent cause of primary sterility was the various degrees of arrest of development of the uterus. Gynecologists found no more difficult problem to solve than the determination in a given case whether the sterility be due to a uterus that was not sufficiently developed. Furthermore, it called for a great deal of experience in bimanual examination to be able to say definitely that the uterus was not of the size corresponding to full development. Still, in the vast majority of cases, one could distinguish a uterus that was so far below the normal as to be the cause of sterility. The reader said that in his experience, the most frequent form of arrest of development giving rise to sterility was that which resulted in a small uterus, not much more than half the size of the normal organ, with the cervix acutely anteflexed upon the body. In those cases, both the cervix and the body were proportionately small. Menstruation, as a rule, set in late, in the seventeenth or eighteenth year, was rather scanty, attended with or without pain and was usually regular until marriage, after which it became irregular, and in the course of two or more years, perhaps, ceased entirely. Such cases were, as a rule, hopeless. He knew of no form of treatment that would benefit them, and he recalled several cases in which great harm had been done by the so-called treatment for developing the uterus. The next most frequent variety was that commonly known as the "infantile uterus," with a long cervix and a very small body, rather acutely anteflexed upon the cervix. Dilatation, and the insertion of a stem pessary for a week or longer, sometimes was attended with a cure in these cases. The prognosis was generally good if the patient was still comparatively young. The third variety was that which was generally described as "congenital retroversion." In these cases both the cervix and body were comparatively long and slender, and seemed to lie in the same axis. The body was retroverted to the first or second degree and considerably to the left of the median line. In these the arrest of development seemed to involve the ligaments, especially the broad ligaments, as well as the uterus. It was this form that baffled most surgical procedures to remedy the existing displacement, owing to the poorly developed and short broad ligaments. The other common forms of malformation on the basis of arrest of development that were usually attended with sterility were (1) a peculiar formation of the vaginal portion known as "conical cervix," and (2) the occurrence of a very minute os externum, known as the "pin-hole os." The former condition was very characteristic and easily recognized, and the results of treatment were usually good if the remainder of the uterus was fully developed. In the latter condition the prognosis was good if the os externum was the only abnormality. Mere stretching was seldom sufficient, some plastic surgery usually being called for. Malpositions of the uterus in the nullipara might exist from other causes than arrest of

development. Pathological anteflexion of the uterus, not of developmental origin was not an uncommon condition and was prone to be attended with sterility. Of the other uterine conditions that might be the cause of primary sterility, endometritis of gonorrhœal or other origin deserved more than passing notice. An endometritis so pronounced as to be a barrier to conception was readily recognized. As a rule, a thorough curettage, together with a cauterization of the erosions that were usually found surrounding the external os, and the maintenance of drainage for a week or longer would effect a cure. The speaker said he thought that endometritis of gonorrhœal origin had been given undue weight as an etiological factor in barrenness. In the treatment of these cases, curettage should be followed by an application of a 20 per cent. solution of silver nitrate to the whole uterine canal, and the cavity then packed with iodoform gauze. It might be necessary to repeat the treatment several times. Acute gonorrhœal endometritis must not be tampered with. Fibromyomata of the uterus were the only growths the reader considered as a cause of sterility. Other growths he thought were such rare etiological factors that they did not merit discussion. Fibroid growths were uncertain factors in the causation of sterility: conception sometimes occurred in a uterus studded with them, while on the other hand a small, single growth might be so situated as to prove an impassable obstruction to the spermatozoa. In speaking of secondary sterility, Dr. Vineberg said the most frequent conditions of the uterus giving rise to it were (1) chronic metritis, and (2) very deep lacerations of the cervix. Other conditions requiring a passing notice were permanent hyperinvolution and atresia of the uterus following a rough curettage during the puerperal period, or a too vigorous curettage with or without the application of a caustic to the endometrium at a non-puerperal period.

Sterility Due to Tubal and Ovarian Conditions.—Dr. J. Riddle Goffe said that from the standpoint of location, the causes of sterility in women might be divided into two classes, namely, the extraperitoneal and the intraperitoneal. After a brief review of the physiology of ovulation and fecundation, the speaker said that the various pathological conditions that obstructed the progress of the ovum from the ovary into the uterus could be properly considered under three heads: (1) Those that related exclusively to the ovary; (2) those that related exclusively to the tube, and (3) those in which the ovary and tube were mutually involved. The ovary might be absent or in a rudimentary state, a most fatal condition for fertility. Complete absence of both ovaries was one of the rarest conditions: the absence of one ovary was not so unusual. The rudimentary condition, in which the organ was devoid of function, was occasionaly found. The most common affections, however, were those that resulted from inflammation, such as atrophy, cirrhosis, and cystic degeneration. When atrophy of the ovary occurred in women during the period of functional activity, it became pathologic. This premature atrophy had also been recognized as the result of alcoholism, syphilis, rheumatism and the acute exanthemata. Cirrhosis of the ovary was usually a process consequent upon an acute oophoritis. It was a form of chronic hyperplasia of the connective stroma, by which the follicles were compressed and eventually destroyed, the ovary being transformed into a mass of connective tissue. This condition not only caused sterility, but was usually attended with severe ovarian pain. As an antithesis to this we had hypertrophy of the ovary. This was usually recognized as the result of former inflammation or chronic congestion. This might affect the Graafian follicles, thus producing a large cystic ovary, or it might confine itself to the stroma, thus forming the first stage of the cirrhotic condition. As the result of more extensive inflammation, the ovary might be surrounded by plastic exudate and adhesions. This condition precluded the performance of its functions. As in the ovary, so in the tube we might have rudimentary development and congenital anomalies. In some instances the tube was found to be impervious, a solid cord throughout a certain portion of its course, or the fimbriated end might be imperforate. The most frequent pathological conditions, however, that were the cause of sterility were catarrhal, gonorrhœal, and septic salpingitis. These inflammations resulted in contorting the tube, or they might destroy the epithelial lining of the tube and so deprive it of its function in facilitating the passage of the ovum. Or agglutination might take place between the walls of the tube, causing permanent obstruction. The most common condition was that in which the fimbriæ, due to the inflammatory process, became agglutinated and the patency of the tube absolutely destroyed. These fimbriæ might even be completely inverted, leaving the end blunt and round—the so-called club-shaped tube. Cases of atrophy of the ovary were beyond the pale of surgical interference. In those cases attention must be paid to the nutrition, not only of the local condition, but also of the patient at large. Local treatment and electricity were of doubtful value, and the speaker said he had more confidence in exercise, especially bicycling and horseback riding. The cirrhotic ovary was more or less amenable to the same line of treatment, although whenever either of these processes was well advanced, it was most difficult to prevent its progress. Hypertrophied and cystic ovaries could only be relieved by surgical interference, and in all these operations the speaker favored conservative methods. Cases of pyosalpinx usually presented themselves not so much on account of the sterility as on account of the symptoms from which they suffered. Primarily, in these cases, the object was to relieve the individual suffering; indirectly to restore or produce a condition in which impregnation might be possible. Just what the scope and limitation of subsequent conservative work upon the tube might be was still awaiting the decision of further experience. It was the duty of every operator, however, to leave at least a portion of one tube in a child-bearing woman, so far as her condition permitted. When adhesions existed, they should be broken up and the organs set free. The interior of the tube should be explored to insure its patency, its freedom from obstructing poisonous material or dried particles of desiccated pus. This could be done by flushing out the tube with normal saline solution or passing a delicate silver probe loaded with antiseptics, such as carbolic acid or the tincture of iodine. When the fimbriæ were inverted it became a simple matter, under a saline douche, to massage the tubes, rotate them between the fingers and by gradually milking them out from the horn of the uterus to their extremity, gradually unfold the fimbriæ and restore the ampulla to its normal condition. This was far better than amputating the tube.

Dr. Herman L. Collyer said it was his practice to examine the semen in every case of sterility, and he had found that in at least 50 per cent. of those cases the men were impotent; some wholly, others partially. The total impotence was usually the result of gonorrhœal infection, while the partial impotence was often due to sexual excesses producing such a depletion of the seminal fluid that only immature cells were found in the semen. He thought that in some instances sterility was due to a lack of affinity between husband and wife.

Dr. Philander A. Harris said he thought the general practitioner could cure fully half of the *curable* cases of sterility. Many cases were curable by simple dilatation of the cervix uteri, the operation to be repeated as often as was deemed necessary. The speaker also mentioned congenital closure of both tubes as a cause of sterility: that congenital closure of one tube was possibly quite common.

Dr. S. W. Bandler said he thought that gonorrhœa was by far the most frequent cause of the various pathological changes that were mentioned by Dr. Goffe. In the vast majority of instances, gonorrhœa in woman was not recognized by the patient herself, by her husband, or by

he physician. In its chronic form, the disease gave most no symptoms, and still it might injure the ciliated pithelium of the tube to such an extent as to prevent the assage of the ovum into the uterus.

Dr. JAMES N. WEST emphasized the question of prophyxis in gonorrhœa. The disease was not only responsible r many cases of sterility, but for many deaths. Every ysician should do his utmost to prevent the spread of s evil. Medical teachers especially should bring home their students the importance of recognizing gonorrhœa the male, and a firm stand should be taken to prevent spread of the disease by marriage.

Dr. GALLANT referred to early masturbation and the ulting loss of sexual vigor and premature ejaculation as ible factors in the production of sterility.

Dr. VINEBERG said that if semen was merely placed on vulva, impregnation might follow. In dealing with ility due to congenital defects of the tubes, the speaker d that he did not think the outlook was very hopeful. me of those cases it was impossible to introduce even finest probe into the tube, and no sort of plastic operan would prove effective. Dr. Vineberg said he would advise any woman to submit to so serious an operaunless there were some other indications than steril- Opening the abdomen means a mortality, to say the t, of one per cent.

Dr. DUDLEY said he was heartily in accord with the sents expressed by Dr. Grandin, although the latter had n a stand that we could not work up to. It took e than the course of a natural life to reform a sex. Dudley said he had seen a number of cases of absence e vagina, and five cases of double vagina: three of the r cases he had seen pregnant, and one of them he had ined twice. The character of the vaginal secretion a very important factor in the production of sterility, must be compatible with that of the male, and the aker said he had succeeded in having quite a number pparently sterile women become fruitful by having the ina injected, at intervals, with a weak solution of rbonate of soda. To show that incompatibility might the cause of sterility, Dr. Dudley cited a case in which a band and wife lived together for twenty years without ing children. They then separated, and each of them rried again. The wife had children by her second hus-d, and the husband had children by his second wife. regard to the passage of the ovum from the ovary into uterus, the speaker said he did not think the tube was only factor in its progression, but that an additional very important factor were the constant intraabdom- movements incident to the act of breathing. In rd to the question of the removal of the tube for extrarine pregnancy, Dr. Dudley said he thought the pendun was swinging toward a more conservative method of ating those cases. After removing the products of conption, he saw no reason why the tube itself should be moved. Even if a second abdominal section subseently necessary for a recurrence of the same condition, would be easier than the first.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

At a stated meeting, held March 2, Dr. Solomon Solis hen and Dr. Randle C. Rosenberger read a paper en-ed "Preliminary Report of a Case of Enlarged Spleen d Liver, with Blood-changes Resembling Those of ti's Disease, Apparently Due to Malaria." They reted the case of a fairly well-developed Italian girl, said be only fourteen years old, but apparently older, o presented enlargement of the spleen and liver, with rked reduction in the number of red cells and percentage hæmoglobin, and no material change in the number or portion of leucocytes. There was reason to suspect alarial infection, but plasmodia could not be found in the lood until after the administration of quinine, when hyline and pigmented, spherical, and ovoid, free and intracellular, parasites, apparently of estivoautumnal type, made their appearance. Hemorrhage occurred from several mucous surfaces. Improvement in the blood-state and reduction in the size of the liver and the spleen took place under treatment, which, in addition to quinine, included arsenic and ergot, as well as ten-minute exposures twice weekly to the *x*-rays. Dr. J. Dutton Steele read a paper entitled "Additional Observations on Retroperitoneal Sarcoma." He dealt altogether with ninety-six cases of the disease, in part collected from the literature and including several under his own observation. The condition, while not common, is likewise not rare. Its onset is insidious and its course rapid. In addition to the emaciation and cachexia that develop in the progress of the disease, the principal symptoms are due to pressure, and they will vary in accordance with the situation of the new growth and the viscera with which it is related. The tumor may undergo degeneration and be the seat of hemorrhage, and thus come to simulate a cyst. The only hopeful treatment is surgical, a successful result having been secured in a small number of cases by this means. Dr. John H. Musser and Dr. Josephus T. Ullom read a paper entitled "A Case of Status Lymphaticus." They reported the case of a pallid boy, about five years old, with translucent skin and visible veins, who, previously well, was seized with intense dyspnœa, together with symptoms of profound shock, death taking place in a short time from cardiovascular failure. On physical examination there were dulness over the upper portion of the sternum, irregular areas of impaired resonance over both lungs and loud bubbling and gurgling râles. Post-mortem examination disclosed, in addition to a large, persistent thymus gland, evidences of a mucopurulent laryngotracheitis, bronchitis, and disseminated bronchopneumonia. Dr. Wm. G. Spiller read a paper entitled "Points of Resemblance between Paralysis Agitans and Arthritis Deformans." He dwelt more especially upon the rigidity of the spine and the extremities, the deformities of the former, the ulnar deflection of the hands, the flexions and extensions of the phalanges. He referred to a case in which the rigidity and the deformities were strongly suggestive of deforming arthritis, although the tremor was equally suggestive of paralysis agitans. After death the lesions of the former condition were wanting, and the absence of definitive histologic changes permitted a diagnosis of the latter.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At a stated meeting, held March 9, Dr. J. F. Schamberg discussed "The Cutaneous Manifestations of Syphilis," illustrating his remarks with lantern-slide demonstrations. He stated that the color of syphilitic lesions of the skin, which is usually described as coppery or as ham-like, is not to be depended upon, as often they are entirely without redness, while other affections of the skin may present such an appearance. Polymorphism of the lesions is a distinctive feature of the syphilitic cutaneous manifestations. Further, the secondary lesions of the skin are generally symmetrical and superficial, the tertiary lesions deep-seated and irregular in distribution, with a tendency to be circumscribed or localized. In the diagnosis, consideration must, of course, be given to the history, the presence or the absence of other evidences of syphilis, and sometimes to the therapeutic test of administering mercury and iodine. Illustrations were shown of various types of syphilitic lesions and also of a number of conditions simulating syphilis. Difficulties in diagnosis may arise in relation to smallpox, psoriasis, epithelioma, acne, and lupus. Dr. J. M. Swan read a paper entitled "Visceral Syphilis." He considered especially the invasion of the lungs, the stomach, the liver, and the kidneys. In any of these viscera the morbid process may result in the formation of gummata or of interstitial fibroid hyperplasia. The symptoms may resemble those of other disorders of the same organs, and the diagnosis will have to be based upon a history of

infection, upon the presence of other characteristic lesions, and upon subsidence of the symptoms under active antisyphilitic treatment. Several illustrative cases were cited. Dr. C. W. Burr presented a communication entitled "Syphilis of the Nervous System." He stated that there are no symptoms distinctive of this disease as occurring in the brain and spinal cord, but that their irregularity and their multiplicity are characteristic. Cranial nerves are often involved, but multiple neuritis of syphilitic origin he deemed rare, if it occur at all. A condition of neurasthenia at times develops i the syphilitic patient, and may require especial attention. The symptoms of syphilis of the nervous system do not set in abruptly, and they may be temporary. Some form of oculomotor paralysis is often an early symptom. Especial attention was directed to syphilis of the vertebræ, which may closely simulate tuberculosis spondylitis. It is of the utmost importance to recognize so-called pseudoparesis dementia, which is due to syphilitic disease of brain and meninges, as this disorder is susceptible of marked improvement if not absolute cure, whereas true paretic dementia is incurable. A similar statement is applicable to other syphilitic affections of the nervous system. Dr. H. M. Christian read a paper on "The Treatment of Syphilis." He expressed the belief that secondary syphilis is wholly and entirely curable, while tertiary syphilis must be considered incurable. He pointed out the difficulty encountered at times in making a diagnosis as between chancer and chancroid, and the wisdom, accordingly, of awaiting the appearance of cutaneous manifestations before instituting treatment for syphilis. When the diagnosis has been definitely established, some form of mercury should be administered, by the mouth, if possible and there be no urgency; through the skin, by inunction or hypodermic injection, in accordance with the severity of the symptoms and the gravity of the conditions presented. The general health of the patient should be carefully looked after. Mercurial treatment should be systematically continued for eighteen months, after which iodine in some form should be administered for an additional six months. Large doses of either drug are, as a rule, not necessary, sufficient only being given to obtain the desired therapeutic results. By this mode of treatment cure should be effected in about 75 per cent. of cases.

Pittsburg Academy of Medicine.

At the regular meeting held March 8, 1904, the President, Dr. Ewing W. Day, in the chair, Dr. John W. Boyce read the paper of the evening on "Myocardial Changes from the Clinical Side." He said that myocarditis had never received the attention to which it was entitled, especially as compared with disease of the endocardium. In fact, even in valvular disease, the condition of the myocardium was the most important element. To illustrate how well valvular lesion might be tolerated, he cited a number of cases, including one in which death occurred, apparently of old age, the patient having had a mitral regurgitation a large part of her life. Clinically it is not possible to draw the numerous distinctions that are noted pathologically, the important question always being whether or no any organic disease is present. Among symptoms a characteristic facies, a loss of general energy, and pain behind the sternum were noted. Physical signs mentioned were, in the pulse, character; in the heart, sounds; lack of quality or abnormal rhythm. Occasionally a mitral regurgitant murmur is present, due to lack of muscular tone. The distinctive points in three cases were related, one being without symptoms, another resembling gastritis, and a third neurasthenia. The paper concluded with a plea for the minute clinical study of such cases, and the application of the knowledge so gained, to weakness of the circulation wherever it occurred, particularly in the course of acute infections. Dr. Eaton referred to a case in the Massachusetts General Hospital, during the service of Dr. Whittier, of a child aged twelve years, with indefinite chest symptoms, who had a history of scarlatina to which the myocardial affection was traced. He has not since seen such cases frequently in private practice, but thinks it well to bear these things in mind. Dr. Pettit thought that our tendency was to overlook causes other than rheumatism for heart troubles. He thought scarlatina was frequently a factor. He reported a case of a minister whom he had frequently examined for a number of years before his death. Three years ago this man contracted la grippe previous to which time no heart trouble existed, but following la grippe, increasing cardiac symptoms were noted, death being due to myocardial changes. Dr. Patterson referred to excessively weak heart associated with influenza. He was not certain whether it was due to toxæmia or not; but thought that in cases in which after health was apparently established, and the heart remained weak, that a myocardial change had taken place. He reported one case, a woman, who after an attack of grip, had a typical myocarditis. He thought that the heart should always be closely watched in influenza, and especially this year, for, though the cases seemed mild yet the heart was often profoundly affected.

Dr. Arbuthnot thought that too much attention had been paid to the endocardium, or, rather, too little to the myocardium. Dr. Montgomery reported a case diagnosed as tuberculous pericarditis. Family history negative. Patient suddenly developed malarial symptoms with chills and fever of four weeks' duration. The patient was emaciated, appetite good. Face sallow with brown spots, almost a leucoderma. Heart seemed slightly dilated; apex beat forcible, low in location, in ninth or tenth intercostal space, and had a splashing sound. The symptoms were not progressive. The patient quit work, went to Florida, and has not been heard from. He asked the opinion of Dr. Boyce and the Fellows as to diagnosis, and especially as to excessive downward displacement of the apex beat. Dr. Boyce said that the forcible, diffuse apex beat and distinct heart sounds refuted the presence of fluid in the pericardium. He did not see any basis for suspecting a tuberculous factor in the case. A rapid tuberculosis is usual when there is a history of sudden onset with chills and fever at the outset; therefore the fact of this patient getting better afterward instead of worse, was against tubercle. Then again the sudden onset of the attack was against valvular disease. He said he would suspect for ulcerative endocarditis with subsequent development of aneurysm of heart. He thought we should analyze our weak pulse into heart and peripheral causes. In cases of myocardial changes, he thought there were some good unchanged fibers that would hypertrophy. In regard to scarlatina he did not wish to lessen the importance of endocardial lesions, but thought usually the muscle fibers were strong.

Dr. Patterson reported a case of an elderly man who had been treated with methylene blue for forty-two weeks by an irregular practitioner. The man died of malignant disease. For some time previous to death the bladder was washed out, and in it were found crystals of methylene blue, varying in size from granules to size of pea. He wished the opinion of the Fellows on the chemistry of this case. Dr. Eaton suggested the possibility of a chemical combination with uric acid.

St. Louis Medical Society.

At the meeting of this society on February 27 a "Report from the Committee on Public Health and Legislation" was presented. The question of the milk supply was taken up and a resolution adopted opposing the ordinance recently introduced in the House of Delegates to take the place of the present law on milk supply. The City Chemist. Mr. Bernays, read a report which showed the quality of milk had improved since the present law has been in force. The law provided for a minimum amount

fat constituent of the milk at 3 per cent., and the port showed that from 55 per cent. to 75 per cent. of e samples examined contained more than 3 per cent. fat. The report also showed that no deposits (dirt, c.) were now found in samples and that coloring matter d preservatives had been eliminated entirely. Dr. bert Merrell of the Board of Health said there were tween seven and eight thousand cows in the city kept in -called dairies under conditions useless to describe. der the present law the conditions had greatly im-oved, and if nothing else had been accomplished than e results as shown by the report of the City Chemist, is alone would justify the support. Another feature the present law was the temperature clause which required at all milk should be delivered to the consumer at a tem-rature not over 50° F., and the samples examined in-ated that less than 10 per cent. of the milk was sold at a mperature above 50° F. The most reliable preserva-e was the promptest possible refrigeration of the milk er it was drawn from the cow and the maintenance of a mperature not over 50° F. Dr. Merrell stated that the dinance recently introduced was solely to permit all sorts sophistication of that questionable fluid called milk. e did not know who drew up the proposed law, but ought it was drawn up by the attorney for the Dairy-en's Association. Dr. Bernays said the ordinance ferred to contained no reference to the fat constituent the milk, and that even if it was watered until it con-ined less than 2.8 per cent. of fat it would be necessary prove that the vendor knew it e so watered, and also that he w it was sold for consumption a food by families, neither of ch facts could be proven. In opinion the ordinance would rd no protection whatever.

On the question of garbage re-oval, the following resolution was opted: "In view of th ineffective d inadequate method by private ntract, as proved by past experi-ce in this city, this society would gest a trial performance of this rk by a carefully regulated nicipal service before recourse is again had to the stem of removal by private contract."

Another ordinance recently introduced in the House of legates was a subject of discussion. This was an ordi-nce providing for a maximum salary of $10,000 per r each for the Comptroller, the Water, Sewer, and eet Commissioners, while the salary of the Health mmissioner was to be only $5,000. The society adopted olutions stating that the public health interests were cond to none in importance and demanded for their oper administration a degree of skill, training, and ability al to those of any other department of municipal vernment, and that the developments and advances protective medicine and sanitary knowledge for the ving of health and life had placed the members on a entific footing unsurpassed by any other, and justified demand for compensation commensurate with the ghtful claims of any other learned profession or scien-ic calling, and deemed unfair the discrimination in salary mpensation against the Health Department as com-ared with the legal, fiscal, and engineering departments.

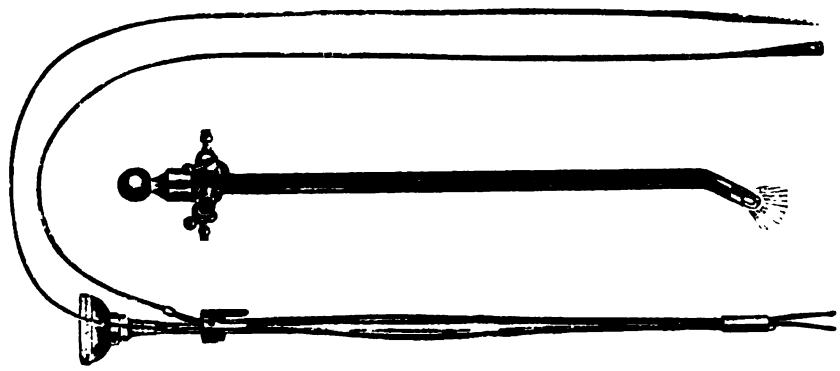
Hospital Fees at Harvard.—A rule has just been assed at Harvard providing that students in the ambridge departments of the university, namely, he college and Scientific School, shall pay $4 each ear for the maintenance of the Stillman Infirmary. tudents in the other departments of the university re not compelled to pay the, fee but can do so if hey wish. The fee gives any student the right to tay in the hospital as long as he is sick.

New Instruments.

A SIMPLIFIED IRRIGATING CYSTOSCOPE FOR OBSERVATION AND URETER CATHETERISM.*

By FOLLEN CABOT, M.D.,
NEW YORK.
VISITING PHYSICIAN, CITY HOSPITAL; ATTENDING GENITOURINARY SURGEON, PRESBYTERIAN HOSPITAL DISPENSARY; INSTRUCTOR IN ENDOSCOPY AND CYSTOSCOPY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

After considerable clinical experience with various cystoscopes, particularly the direct-view type of instrument, I have devised the instrument I am about to demonstrate clinically before the society. My chief aim in devising this instrument has been to make it as simple as possible, and yet without sacrificing any of its usefulness. In carrying out this idea, I have, I believe, sacrificed no essential parts and have added something, I hope, in the way of a very practical and easily handled direct view cystoscope for irrigation, observation, and ureter catheterism. The sheath of the instrument, as can be seen, is somewhat oval in outline, is of the calibre 24 French, and is very easily introduced into the male bladder. As in the Brenner cystoscope, one telescope only is used for both observation and ureter catheterism. Like the Brown instrument, it is arranged for catheterism of both ureters at the same time. Owing to the ovoid form of the sheath, room is saved, and



permits of a larger telescope for ureter catheterism than in the Brown instrument. This larger telescope gives a sufficiently good field also for observation. In this way it makes a change of tubes unnecessary. The ureters are more easily found, and without change of telescopes we are in a position to catheterize them immediately. This is an important matter, as I have by considerable experience found. The catheters, which should be twenty to thirty inches long and black at the ureter ends, lie in the bottom of the lumen of the sheath, and are held in position by the telescopic tube above and the sheath below and on the sides. No separate chambers being used except at point of entrance for a half-inch. The catheters are carried to the end of the telescope and supported there by a bridge undivided and one-half inch long. This gives a point of fixation in introducting the catheters into the ureters. The absence of separate chambers for the catheters has served the purpose of making the instrument very easy to clean and somewhat simpler, but most important of all it permits of the easy withdrawal of the cystoscope, leaving the catheters in the ureters. It is done, as I shall demonstrate to the society, in the following manner:

After the catheters have been introduced into the ureters 4–6 inches, the telescope is withdrawn from the sheath for about three-quarters of an inch. This movement permits us to grasp the exposed

*Demonstrated at a meeting of the Harvard Medical Society of New York.

catheters with the left hand and with the right pull the telescope the rest of the way out. At the end of the telescope we come to the bridge. Here we lose half an inch, then completely withdraw the telescope. We now have thrown our two catheters into the lumen of the sheath. The sheath is now easily withdrawn as we feed the catheters into its lumen. The catheters now alone remain, one in each ureter, protruding from the urethra. We can in this way collect as much urine as we wish, leaving the catheters in place several hours if necessary. The importance of removing the instrument in some cases is considerable, making the discomfort to the patient so much less. In fact, many patients cannot tolerate the cystoscope long enough to allow us to collect sufficient urine for examination.

Before introducting the cystoscope we should always test the light; then after attaching rubber tubes 6–8 inches long on each irrigation cock, we put the obdurator in place, introduce the instrument very gently, then, by the use of a 3½ piston syringe, fill the bladder through the irrigating attachment. A warm boric-acid solution, about 2 per cent., is the best. The telescope is now put in position with the catheters in place, and after it has been screwed in place the light is turned on. If necessary we can now add more warm boric acid solution. We should, if possible, use from 4 to 6 ounces of fluid, but much less can be employed with success. Air in certain cases may be used in place of fluid for distending the bladder.

In conclusion I may say that this cystoscope is extremely simple, is easily introduced, can be used in male or female, is easily cleaned, is very moderate in price, and fulfils the conditions I have spoken of very well. The Wappler Electric Controller Co. of New York are the manufacturers. The lamps are cold, and are therefore free from any danger of burning the bladder or urethra.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 19, 1904:

	Cases.	Deaths.
Measles	1454	35
Diphtheria and croup	406	40
Scarlet fever	491	28
Smallpox	...	1
Varicella	102	...
Tuberculosis	457	209
Typhoid fever	29	9
Cerebrospinal meningitis	...	16

Lumbago.—Sir W. Gowers suggests that diaphoresis should be resorted to early; also hot fomentations and rest is very essential. Massage and electricity should not be used at first; when used, a very mild Faradic current is the best form. A saline in the morning is very important. Salicylates have little influence; the best drugs are nitrous ether, citrate of lithium, and colchicum in the early stages. In very severe cases daily injections of cocaine are useful.—*British Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S Marine Hospital Service, during the week ended March 19, 1904:

HIP AND THIGH AMPUTATIONS FOR SARCOMA OF THE FEMUR.*

BY GEORGE F. SHRADY, M.D.,
NEW YORK.

The well-known malignancy of sarcoma of the femur, for which hip amputation is the only and often ineffectual treatment, invests with peculiar interest the following case of absolute cure of the disease by the simple thigh operation:

The patient, a native of New Brunswick, N. J., was twenty-two years of age when he consulted me in October, 1882, for the treatment of a tumor situated over the inner condyle of the left femur. During the winter before he injured his left knee by accidentally jumping on a snow plow. The pain and swelling from the bruise disappeared after a rest of a few weeks and he suffered no inconvenience until the following August, when a new enlargement on the inside of the joint appeared and was supposed by his attending physician to be due to commencing scrofulous disease. When the patient was admitted to the hospital two months after this diagnosis had been made he presented a well-defined nodular elastic growth in the situation indicated, and firmly attached to the bone. The diagnosis of osteosarcoma was made and amputation at the hip was advised. Not being willing to submit to such a radical measure, he returned home in the hope of obtaining relief from his suffering by other means. He remained away for a month, during which time the growth had increased and the persistent and increasing pain had necessitated the constant use of morphine. He still objected to hip-joint amputation but finally consented to removal of the thigh. In order not to leave the least vestige of doubt as to the character of the tumor, an exploratory incision was made immediately before the operation, when the growth was found to be a subperiosteal spindle-cell sarcoma. The section of the limb was made near the hip as far as possible from the diseased parts.

The specimen was presented to the New York Pathological Society at its meeting December 13, 1882, and showed the usual and characteristic appearances of a subperiosteal growth involving at one point the medullary cavity. At that time, in the course of a discussion on the malignancy of the tumor, I stated that the prognosis of the patient was so grave that I had but little, if any, hope that he would escape a recurrence or a metastasis. Strange to say, however, no subsequent trouble ensued and he is still alive and well, now over twenty-one years after the operation. It seems quite warrantable then to state that the cure is complete, even after simple amputation of the thigh.

Not only is the case unique as to the time which has elapsed since the operation and the fortunate opportunity of verifying the fact, but in some other respects the study of some of its features may, perhaps, bear on the prognosis in similar conditions when ordinarily there would appear to be no hope of ultimately saving life. Recurrence or metastasis is the rule in sarcoma. Why one or other should not occur in a well-developed case such as this one is somewhat of a mystery, and still more strange is it that the disease should be cured short of entire removal of the affected bone. When it is understood that the distribution of the disease is by means of cell elements in the blood current, it is easy to assume that there is some chance for the patient when the original growth is firmly encapsulated and confined to comparatively narrow limits. In support of such a supposition it is amply proven that when once the barrier is broken down extension and metastasis take place with great rapidity. So far, then, this disposition gives the most forcible argument for the early operation. It is quite evident in the present instance that the amputation proved effectual because it happened to be performed at a time when the growth was absolutely localized and circumvallated. Although this may be a reasonable explanation for non-recurrence of the disease, there is, however, never any absolute guarantee against the ready spread even of an early recognized growth, as perfect encapsulation is oftener the exception than the rule in such cases. Still it must be remembered in this connection that there is not so much liability to metastasis in the small spindle-cell sarcoma as in the giant round-cell variety.

Bearing also on this phase of the question it is a well-acknowledged fact that exploratory cuts into these tumors are very apt to be followed by metastases. The reasonable explanation for this is the escape of the free colonies of cells into the freshly opened mouths of the blood-vessels and into the lymph spaces of the contiguous cellular tissues. Such incisions, however, were made in the present case and no harm followed. Obviously the danger of dissemination would be greater in proportion to the time allowed to elapse between the preliminary incision and the subsequent operation. The argument would thus be in favor of the exploration immediately before the operation, as there should be no excuse for a mistaken diagnosis in view of possible loss of opportunities in other directions. The adoption of such a measure has saved many limbs which might otherwise have been ruthlessly sacrificed. On general principles, then, this practice should be the rule at any risk.

The relation of traumatism to sarcoma is quite well established, especially in connection with tumors of the extremities, but why the same kind of injury should occasion the disease in one person and not in another is still somewhat of a problem. This leads us quite naturally to the consideration of the question of hereditary predisposition to neoplastic growths in certain individuals. Although this has not been definitely proven, the question is still open along more than merely conjectural lines.

The embryonic theory of Cohnheim still has its advocates in spite of the more recent one of microbic infection. Neither, however, can hold its own in the face of our present pathological views of malignancy

*Read before the Practitioners' Society, February 5, 1904.

in tumors. Behind all arguments for or against either view it must be assumed that there is a certain susceptibility to neoplasms in some individuals and not in others.

Each cell composing the body must have a vitality of its own whereby its destiny of differentiation and adaptability to systemic requirements is determined. These relations may be disturbed at any time, and a reversion may take place in consequence, the cell elements assuming embryonal qualities and atavic proclivities. When the process is once started there is a riotous disposition to ignore all laws of normal development. What lends force to such a conjecture is the fact that the determining cause of malignancy must be always direct and local.

This is substantially Ribbert's theory of malignancy in tumors and has many points of plausibility. In connection with Weizert he first published his observations in 1895 (*Deutsche medizinische Wochenshrift*), and further elaborated them in the same periodical in December, 1901. It may be called the theory of cell-disassociation, as distinguished from the strictly "organic" relation of cell development.

Among the causes that could give rise to this disturbance, Ribbert mentions simple inflammation, traumatism, and replacement hyperplasia, with of course the admission of some sort of predisposition in the affected tissue. If speculation could be carried farther, we might apply the ion theory of disturbed relations of vital forces in the implicated cells in explaining this misdirected activity. In spite of the ingeniousness of this theory, it must be admitted that it does not account for all the conditions of clinical experience, as by the adoption of the hypothesis as a whole it would be impossible for any patient to be safe from a recurrence of malignancy in any inelective part of the body, even after the original localized growth had been effectually extirpated. Granted a general receptive quality in his tissues, the slightest provocation might start a malignant growth entirely independent of the original trouble. As it is, however, we can, clinically at least, always trace a direct relation of such growths to the primary tumor as if demonstrating a distinct local receptivity in each individual. It is the question of the leaven spreading gradually through the lump after having been started in the given direction.

What appears to be a fundamental objection to the parasitic theory of malignant growths is the claim that a specific infection is capable of instigating an active proliferation of entirely new cell tissue totally different from any other process known to biology. Under all other conditions of infection Nature resents the invasion by leucocytosis, phagocytosis, and the action of the antibodies. By such protective agencies it strives to overcome the complicated local and systemic influences of the attacking poison. The false membrane in diphtheria and the tubercle nodule of consumption are striking instances in point. In both these are the elements of resistance and defence, but not a disposition to produce new tissue capable of propagating itself on its own account.

The law of cell development as applied to normal or even neoplastic tissue growth is strongly opposed to such an hypothesis. The greatest drawback of all is that no parasite has yet been demonstrated to prove any such relations of cause and effect.

Not even in cancer, in which there have been so many attempts to inoculate the disease, has any distinct success crowned the efforts of experimenters. It is true that the cell elements have been transplanted from one animal tissue to that of another, but this was by a species of engrafting rather than by inoculation. The experiments proved, perha that there was in these cases merely a local rec tivity to independent cell action. What more we say while swinging around the circle of conj ture?

Great is the pity, then, that in the present st of our inquiries the parasitic theory has no stronger hold on plausibility, inasmuch as its ab lute substantiation might afford new hope for cure of what is now considered the most formida and intractable of maladies.

To descend, however, from theory to fact, the m interesting point of all connected with the pres case is the cure of the patient in the face of alm overwhelming previous testimony against such possibility.

So far as can be learned by a reasonably exha tive study of statistics, it appears to stand virtu alone as an instance of cure after simple amputat of the thigh. Even in hip amputation the num of recoveries is very small.

Mr. Henry T. Butlin, whose thorough study operative procedures for malignant growths made him the leading authority on the subject, collected sixty-eight hip amputations for sarc of the femur and has been able to find but one that remained well sufficiently long to be con ered cured. In answer to a recent request for further data he writes under date December 1903:

82 HARLEY STREET, LONDON W
DECEMBER 23,

I am much interested in your letter, and shall forward to the publication of the case.

I have not been through the latest literature on periosteal sarcoma of the femur; for I have not had sion to do so, and have been very busy in other direct But, I am sorry to say that the results of amputatio subperiosteal sarcoma of the femur have not, in my e rience, improved in the least since the second edi of the "Operative Surgery of Malignant Disease" published. The last cases which I directly publis so far as I remember, were recorded in the *Practitioner* the year 1896. They were published chiefly for the of the radiographs. All the three young women suff from subperiosteal sarcoma. In two of the three I formed the (thigh?) amputation, while the operation the hip-joint) in the third was performed by Mr. San of Oxford.

I amputated very high above quite moderate circumscribed disease, so far above it, that the inci passed through the bone some two inches or more ab the well-defined upper limit of the tumor in the interi the bone. But, in both these cases, there was quite e recurrence and generalization of the disease. In the th case, where the amputation was performed at the joint, the fatal result was deferred for a much longer ti although the primary disease had existed much longer the extent of the disease necessitated an amputation at hip-joint.

I shall certainly advise amputation at the hip-j when my opinion is asked in a case of this disease.

Your case is the more interesting because the amp tion was performed through the thigh. But, it is so g an exception to the general rule that I am afraid it m not be used as an encouragement to amputate through thigh in similar cases.

Dr. W. B. Coley, who also has given much stu to the subject, especially in connection with the of his toxins for inoperable cases writes:

5 PARK AVENUE, December 11, 190

In reply to your letter of the 10th inst., in regard your case of amputation of the thigh for periosteal coma of femur, well twenty-one years afterward, I wo say that the only cases of probable cure of sarcoma of femur known to me, are the following:

1. Case of sarcoma of the lower end of the fem operated upon by Dr. D. H. Agnew, sixteen years ago (h joint amputation). Patient is still well.

2. Case of osteosarcoma of the femur—amputation the hip-joint by Dr. Wm. T. Bull, at the New York H pital, followed by severe infection of the stump—probab streptococcus. Patient well six years afterward.

3. Periosteal sarcoma of the lower end of femur, case Dr. J. D. Rushmore of Brooklyn. Patient, a girl irteen years of age, whom I saw in consultation and vised amputation at the hip-joint. The case was well en last seen, five years after operation.
4. Osteosarcoma of the femur. Amputation at the -joint performed by Dr. W. L. Robinson of Danville, ., in 1898; the mixed toxins given as prophylactic er operation. Patient remained well for over three rs; then had a recurrence in the iliac fossa, which ppeared under renewed toxin treatment. The patient s well when last heard from.
5. Case of Dr. A. P. Gerster of New York. The ient, a girl of about twenty, was considered beyond putation four years ago and was treated with the mixed ins with entire recovery. The patient is well at present. roscopical examination in this case was made by Dr. ndlebaum and confirmed by Dr. T. M. Prudden, the ase being pronounced typical giant-celled sarcoma.
I have performed hip-joint amputation in seven cases, e times for sarcoma of the femur, twice for sarcoma he thigh. The only case that has remained well over e years is a sarcoma of the thigh. In this case the ns were used.

Dr. Frederic S. Dennis (*Medical News*, January 1888), who has also collected large number of tistics and has performed several hip amputa- s for femoral sarcoma, reports no recoveries.
Dr. John A. Wyeth (*Journal of the American Medical ociation*, May 18, 1901), in a paper on "Hip-joint putations," has tabulated 267 cases performed by method. Of these 131 were for sarcoma of the ur with only five test recoveries exceeding the e years' limit of non-recurrence.
he whole number of successful hip cases that re- ed well three years and more after the opera- amounts to barely eleven. Weir and Griffith one free for over three years, Freeman and ley 1 each for 4 years, Rushmore 1 for 5 s, W. T. Bull and Shropshire 1 each for 6 s, Phillips and Dugan 1 each for 7 years, Sherman 9 years, and D. Hayes Agnew 1 for 16 years. lo not include in these the cases of Robinson and ter as reported by Coley, inasmuch as in one s was a recurrence and in the other no amputa- was possible, the ultimate cures, according to y, being due to to the use of the toxins.
the theory of dissemination of sarcoma is at all ble it should have a bearing on the kind of opera- that should be performed. On general princi- it follows that so long as the disease is limited given locality the removal of the affected part that is necessary to ensure a cure. Contrari- when metastasis occurs no operative procedure any benefit. Also when a tumor is situated on xtremity amputation should give the best pos- guarantee of thorough extirpation of local dis- , provided the parts through which the section is e are unaffected. There are, in fact, no other anations for recoveries after a single operation. ay be surgical heresy to ask why a thigh ampu- n under such favorable circumstances should be as successful as the one so generally advised he hip, but the question is not without its sig- ance.
t does not prove because hip amputation may e been successful in eradicating the disease that ething short of it would not do as well. Other- hip amputation would be uniformly successful. we know is not the case, recurrence taking place st as frequently in them as in the thigh amputa- s. An explanation for the latter conditions ht be offered on the ground that after the medul- y cavity of the bone becomes invaded there is no re chance for one operation than the other.
ut this is not so plausible as at first sight it might n to be. It cannot be proved that the marrow the principal medium of neoplastic cell dissemina- n. On the contrary the extension of disease in the medullary cavity of a bone is a comparatively slow process even in central sarcomata. Nature makes every effort to wall in the growth by adventitious material and even throws out extra bulwarks of new bony tissue to that end. Hence the direction of concentric expansion is through the compact bone rather than longitudinally along a comparatively easy and otherwise unresisting course.

A secondary invasion, however, of the medullary cavity by extension of a subperiosteal growth implies destruction of intervening bone and a corresponding infiltration of contiguous soft parts. When this occurs the growth is no longer a local one and general dissemination is inevitable. The mere invasion of the marrow is thus a matter of secondary consideration, as the migrating cell colonies have already taken another route.

It necessarily follows then that the surgeon must always take the chance of operating at the only fortunate time when a thigh amputation might be as successful as one of the hip.

Personally, I am strengthened in this conviction by noticing the frequency with which the metastasis occurs while the stump wound remains free. When there is a local return of the disease it is obvious enough that the original growth was not entirely extirpated, but this fact is in no sense an argument in favor of removing the entire femur or nothing, any more than insisting upon a primary resection of the thoracic wall for mammary cancer, in the fear of recurrence in the contiguous intercostal spaces.

In the majority of instances it is entirely a question of either primary or secondary involvement of the soft parts rather than of the bone, and for obvious reasons is gravely significant of a rapid and uncontrollable dissemination of the disease through the general blood current by other and outside channels. This occurs in hip as well as in thigh operations and for like reasons. In both instances it merely proves that the disease was from the first beyond the point of bone section or that of the disarticulation.

Granting these conditions, it would seem that so far as the point of bone section is concerned the only necessary thing to be accomplished would be to get safely clear of its actually diseased area, as under other circumstances any attempt to be extra-conservative would surely result in a local recurrence from a culpably incomplete operation.

The point of the argument then rests upon the assumption that the bone, although primarily diseased, is not necessarily and in itself the essential cause of systemic infection, and that the failures to cure by amputation of any kind are due mainly to the secondary influences acting upon the general blood current through infiltration of adjacent soft tissues. The rapidity of infection is only paralleled by its hopelessness. When once started it is not a slow process, as in the gradual and progressive infiltration of cancer, but a quick transfer to the nearest filtering organ.

Hence the first lodgment by a very direct route, is usually in the lung, and obviously enough this is the case most frequently in thigh tumors, thus emphasizing their well-recognized and widespread malignancy. But this does not disprove the limitations of danger when the disease is strictly confined to the periosteum or bone. In furtherance of this view no less an authority than Mikulicz goes so far as to advise simple resection in some cases. In one instance in which such an operation was performed by that surgeon on the femur, and in which subsequent amputation was necessary on account of the unserviceable limb, neither end of the affected bone showed any evidence of involve-

ment, but on the other hand there was an entirely new formation of healthy osseous structure. Certainly there was no necessity under such circumstance of removing the entire bone.

Coley (*American Medicine*, January 9, 1904), who is an advocate of hip amputation, quotes this case to offset it with one of Bull's, in which the entire medullary cavity was affected, and in which disarticulation of the affected bone was followed by recovery. But it so happened that the conditions were entirely different and each surgeon did a perfectly proper operation. In both instances the bones only were involved. This, after all, is the main point to be considered in all our cases, and if any studies tend to make us more careful and judicious in the selection of any operative procedure, we are certain to be repaid in the end for the time spent and the trouble taken. I am not to be understood as opposing hip disarticulation for sarcoma on general principles, but as attempting to show why simple thigh amputation may sometimes succeed. Also that there are few, if any, objections against the thigh amputation which may not apply to the complete removal of the femur. In other words, I have endeavored to explain why my patient recovered in spite of an overwhelming probability to the contrary.

THE DIAGNOSIS OF THORACIC ANEURYSM.*

By CHARLES E. NAMMACK, M.D.,
NEW YORK.
VISITING PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK; OUT-PATIENT PHYSICIAN TO THE NEW YORK HOSPITAL.

ANEURYSM is a more or less circumscribed dilatation of an artery, as distinguished from the uniform widening of an artery, which results from sclerosis. It may occur in the course of any artery in the body. Hence aneurysms may vary in size from the microscopic, or barely visible, to the large aortic tumors which take up a large part of the thorax and abdomen. Excluding the very small, or so-called miliary aneurysms, aneurysm in general is a rare affection. My personal conviction is that it is not so rare as has been stated by Whittaker,[1] *i.e.* that in a million of men there may be one aneurysm. Its rarity in Continental Europe may be due to the fact that the same strenuous life is not forced upon the people there as by the keen competition existing in these United States. As a rule, the wards of Bellevue Hospital, with 850 beds, contain at least one case of aortic aneurysm. During sixteen years' service as surgeon of police, I have encountered but two cases, notwithstanding the fact that the pathogeny of aneurysm is closely related to that of arteriosclerosis, and that cases of the latter disease are frequent, on account of the irregular hours, inordinate appetites, and continuous mental strain under which police officials exist. The essential etiological factor in aortic aneurysm is some diseased condition of the vessel wall. This diseased condition is most frequently an arteriosclerosis, caused by syphilis. When this condition exists during middle life of the patient, and during the stage of primary degeneration and weakness of the media, before compensatory thickening of the intima has taken place, any sudden physical strain, a sneeze, a cough, or sudden exertion in lifting or moving, may be the starting point of aneurysm. It is only the infrequency of conjunction of these causes that accounts for the rarity of aneurysm. The atheroma of old age does not favor its production. The development of aneurysm, after a sudden physical strain, may be so insidious that months may elapse before definite physical signs are manifest.

*Read before the Celtic Medical Society, December 22, 1903.

The marked influence of syphilis in causation been recognized from the earliest times, but is pr ably overrated. Its reputation in causing the gr number of cases in the English Army receive correction when Barwell showed that aneurysm thirteen and one-half times more frequent in army than in the navy.[2] It is inconceivable that relative morality in the two arms of the service i 13½ to 1, although it must be conceded that opp tunities for the acquirement of syphilis occur m frequently to Tommy Atkins than to his brot who goes down to the sea in ships.

Next to syphilis, alcohol is the most freq cause of the arterial disease which leads to aneury It has been shown that during the temperance sade in Ireland the number of hospital case aneurysm decidedly decreased, to increase a when it was over. Gout and rheumatism are potent factors in producing arterial degenerat Osler[3] points out that there are many cases in wh no definite cause can be made out, but in which individual shows a tendency to arterial dise probably from defective quality of the arterial ti which he has inherited.

The symptomatology of thoracic aneurysm i variable that its recognition may be one of easiest problems of clinical medicine, or it may b indefinite and obscure as to defeat the most sk diagnostician. The phenomena produced ma divided into two groups: (1) The direct sympt which are confined to the limits of the tumor i and which are termed the physical signs. (2) indirect symptoms, due to mechanical pressur the parts surrounding the tumor. But each g of symptoms is always latent for a time, and s times latent for a long time. Pain is the most pr inent, persistent and characteristic symptom. may be light or excruciating, paroxysmal or sistent, and has diagnostic value when unus persistent or severe. At the beginning it is us mistaken for intercostal neuralgia, or pleurod or rheumatism; but a noteworthy point is that pain is increased by exercise, coughing or snee mental excitement, or anything which increase activity of the circulation, or raises the b pressure. If the aneurysmal sac develops "ce fugally," that is toward the surface of the chest, appears earlier, is more constant, more neuralg character. It will also be intensified by any po which permits the sac to gravitate or press strongly upon the irritated and painful nerve.

Many cases begin with palpitation, disturbed action being of frequent occurrence throughou whole course of the affection, although organic diac disease is the exception and not the rule. sure signs may be very numerous and variabl the aneurysm encroaches upon contiguous struct The most constant of these signs is brachial ne gia, due to pressure on the brachial plexus. Ho ness or aphonia may result from implication o left recurrent laryngeal nerve. Pressure up bronchus or upon the trachea produces dysp often accompanied by loud stridulous breathing by harshness and a metallic quality of the v Dyspnœa also results from pressure on the nerv the larynx and may be constant, paroxysma spasmodic. Extreme pressure on the lung may rise to all the signs of solidification. Distenti the cervical veins, and œdema of the face, neck upper extremities may indicate pressure upo superior vena cava or innominate vein. Com sion upon the inferior vena cava would be indi by distention of the abdominal veins. Dyspl may be caused by pressure on the œsophagus. T the aneurysm is on the concave side of the a

ssure on the pulmonary artery produces severe pnœa, systolic pulmonic murmur, and accentud second pulmonic sound. Pressure upon the racic duct is relatively rare. Pressure upon ghboring bones causes erosion, absorption, and disation. Myosis and other pupillary abnormalities significant, but not pathognomonic of aneurysm. he direct symptoms, or physical signs, relate first he tumor itself. This is soft, yielding, and may metimes be emptied by pressure when accessible ernally. Expansile pulsation may be felt in it, on all sides of it. A peculiar purring thrill is characteristic. On auscultation a bruit, which been likened to "the passage of water through pipes of a fountain," may be heard. Any change he heart structure belongs to complications rather to aneurysm, but some dision of the heart apex is l, from the pressure of the rysm at the base. The pulse be retarded at the wrist, or ced in volume up to disearance in the radial or car- on one side, or diminished rce. These differences be- most distinct when the arm d up vertically from the body, hey may be observable only he aid of the sphygmograph. pulse, taken by itself, does however, contribute very ive evidence of an aneurysm. inspection of the chest then, ave dislocation of the heart , pulsating tumor, later eroof bones. Palpation appreci- more distinctly the change in beat, expansile character of tion, and characteristic thrill. heal tugging may be felt in y cases, but is not pathogomic and may be entirely misng. Percussion shows dul- directly over the aneurysm, absence of dulness does not ude aneurysm, as the tumor be so deep-seated as not to h the surface at all. Auscul- n reveals the characteristic it, but not in all cases. Some- es the normal heart sounds be heard distinctly in places re they are usually inaudible eeble. A fundamental rule in examination of a suspected of aneurysm is to auscultate r every inch of the thorax, nt and back, always remember that aneurysms do not always duce acoustic phenomena. In e cases a bruit can be heard only when the bell he stethoscope is held between the patient's teeth, murmur being transmitted through the column ir in the trachea. Another important point is rough inspection of the chest, front and back.[8] The diagnosis is determined by the recognition of sative conditions, the symptoms, and the physiexamination, remembering that it is not justifia- to assume the existence of aneurysm in the ence of expansile pulsation. Any tumor lying oss an artery will have pulsation communicated it, but the pulsation will not be expansile. Aneum of the ascending part of the arch of the aorta es the most distinct physical signs, pressure signs ing more distinct when the descending portion is affected. Aspiration of the tumor may be required as a final test, in some cases. The value of the x-ray in diagnosis is considerable.[8] Some aneurysms can be more positively demonstrated in this way than by any other.[9] In the two cases presented this evening, skiagraphs show very clearly the location and size of the tumors. As a possible means of early diagnosis Wm. Porter of St. Louis[4] advocates the passage of an œsophageal tube distended with water and connected with an outside U tube in which distinct vibrations can be seen and estimated. The danger of this method would seem to outweigh its advantages. Dr. A. Symons Eccles[6] calls attention to the frequency of a sensation of dread, faintness, or giddiness when the head was thrown back, as in shaving, and which he attributes to increased tension on

Fig. 1—View from behind. Case I.

the thoracic vessels. I have personally verified the accuracy of this observation as an early sign of thoracic aneurysm, in three cases, long before its existence could be demonstrated by physical signs.

In the differential diagnosis, it must be remembered that there are other thoracic conditions which produce groups of symptoms closely resembling those of aneurysm. The most frequent and important are: (1) Solid intrathoracic growth, such as carcinoma or sarcoma; (2) abscess or tumor of the mediastinum; (3) pulsating empyema. Malignant tumors grow more rapidly than aneurysms, are accompanied with more pronounced emaciation, and loss of strength, and their pulsation is not expansive in character. These tumors have not the erosive

properties of aneurysm. In addition, we may have the history of antecedent tumor elsewhere, or induration of neighboring lymph nodes. Mediastinal abscess is apt to be of sudden invasion, pain is an early symptom, and fever is likely to be present early. Leucocyte count will also be of service. Pulsating empyema in immediate contiguity to the heart may be determined by introduction of very fine needle.

Other conditions in the aortic area, such as aortic regurgitation with dilatation of arch, aortic stenosis, hypertrophy of the heart, may all be differentiated by careful reading of the physical signs. Mediastinal solid tumors are generally mistaken for aneurysm, although they do not furnish the characteristic thrill. But one of the mistaken notions of clinical

FIG. 2—View from in front. Case II.

medicine is that aneurysm will invariably furnish thrill and murmur. E. Gebauer[6] puts on record a case in which all symptoms, signs, and *x*-ray examination pointed to aneurysm, but post-mortem study showed a round ulcerating carcinoma of the œsophagus with a communicating abscess cavity adherent to the posterior wall of the aorta. P. Hamplen[7] lays especial stress on the value of tracheal stenosis as pointing strongly toward aneurysm of the arch or trunk of the aorta, rather than to mediastinal tumor.

The prognosis is always grave, but not necessarily fatal, as cure may result from obliteration of the sac by layers of coagulated blood. The aim of treatment is, to secure this coagulation, by retarding the circulation and lowering the blood-pressure. Unfortunately, this happy result is not often attained either by nature or art. The injections of gelatin from which so much was hoped, have been found by most observers to be not very useful and, at the present time, their use has been abandoned in hospitals generally. At the present time, absolute rest in bed, limitation of food and drink, and the administration of iodides in fair but not large doses will accomplish all that can be hoped. My personal opinion is that 15 or 20-grain doses of potassium iodide, given three times a day, are as efficacious in larger quantities, in this disease. Surgical procedures which have been employed, such as filipuncture, needling, electrolysis, ligature, and compression, do not promise much in thoracic aneurysm. This is not strange when one considers the pathology of the disease.

No better illustration of the fact that the sword of Damocles is suspended over the heads of these patients can be given than the fact that two days before this meeting, a man who had promised to attend, went to church as usual, came home, expectorated two cupfuls of blood and was dead in twenty minutes. His history was as follows:

CASE I.—Partick B., thirty-five years old, single, freight-handler by occupation; uses alcohol very moderately; denies all venereal diseases. No evidence of syphilis, gout, or rheumatism. While guiding a loaded coal-scoop into the hold of a vessel, it swerved and threatened to crush him against a stanchion. By bracing himself he managed to stop its swing, but felt the muscular strain for some time after. Nine months ago, he was treated for cough and chest pains, under diagnoses of bronchitis and muscular rheumatism.

On October 12, 1903, he consulted me for the same symptoms. Physical examination: slight heaving of upper part of sternum. Apex beat one inch outside and one inch below nipple line. On the back, pulsating tumor between the vertebral border and scapula and spinal column, as shown in accompanying skiagram made by Dr. Buzby, *x*-rayist of the New York Hospital. Palpation shows expansile character of pulsation, and characteristic thrill. No tracheal tugging. No marked changes in radial or carotid pulse. Auscultation negative. No pressure signs in lungs, œsophagus, larynx, or eyes. Unilateral sweating of left side of face. Patient was sent into the wards of the New York Hospital, but declined to remain longer than three weeks, as his pain and cough had been relieved by rest. In this case, the pathogeny was an outside cause, *i.e.* trauma. The diagnosis was clear and apparent by inspection only. The termination was unexpected.

CASE II.—Joseph B., thirty-eight years, married policeman; drinks freely. No venereal history nor evidence of past infection. Never had gout or rheumatism. Reported sick, the day after election day, on account of hoarseness, cough, and sub

nal pain, all of which he attributed to being on
r for twenty-one consecutive hours. Insists
he was perfectly well up to that time. Physical
nination: Inspection shows labored breathing
mpanied by audible stridor aggravated by
ing around the room, and by dysphonia and
y cough. No bulging of chest wall. The right
of the chest is retracted and perceptibly smaller
its fellow. Dislocation of heart apex down-
l and to left, but not "two hearts beating in the
t at the same time." Expression anxious.
ls regular and equal. Palpation reveals marked
uality of radial pulses. No tracheal tugging.
ussion produces dulness over upper third of
um, and the normal note over both lungs in
t and behind. Auscultation does not detect any
t, even when the bell of the stethoscope is held
e mouth. The heart sounds are heard distinctly
tolerably loud in the left supraspinous fossa.
x-ray picture, by Dr. Buzby, shows the location
ize of the tumor, and completes the diagnosis of
rysm of the transverse arch of the aorta.

contrast with the preceding case, the pathogeny
was an intrinsic cause, to wit: arteriosclerosis,
bly dependent upon alcoholism. The diag-
could be inferred from the pressure signs, and
d by the *x*-ray examination. The course has
steadily progressive.

MODERN TREATMENT OF DACRYOCYSTITIS.*

BY ALFRED WIENER, M.D.,
NEW YORK.

ANT SURGEON IN THE OPHTHALMOLOGICAL DEPARTMENT OF ST. LUKE'S HOSPITAL CLINIC.

extreme conservative attitude which is still
n by a great number of surgeons, in the treat-
t of catarrhal affections of the lacrymal sac, has
me to express my own, as well as to emphasize
pinion of those who favor a more rational and
al treatment of this class of cases. The lacry-
sac, located as it is at the lower and inner angle
e orbit, in the lacrymal groove, serves for the
tion of the tears after they leave the conjunc-
It represents the upper dilated extremity of
nasal duct. Just where the nasal duct begins
the sac terminates, we find the narrowest por-
of this canal. It is here that we most often
with the stricture, which causes such serious
ble in the sac. We have, in this location, when
sed, a source of infection which proves itself
ble of doing great damage to the eye, in some
s accomplishing its actual destruction. The
llest defect on the surface of the cornea, like an
ion, heals rapidly if the eye is bandaged for
nty-four hours. Should a blenorrhœa of the sac
present, at once it becomes infiltrated with in-
ious material, and the cornea suffers more or less
ruction with permanent damage to the eyesight.
t the contents of such a sac is capable of produc-

*Read before the Manhattan Medical and Surgical ciety.

ing an inflammatory reaction is often shown by a co-existing catarrh of the conjunctiva and the lids. In three-fourths of the cases known as "hypopyon keratitis," in which the eyesight has been more or less destroyed, dacryostenosis has been the cause of the infection in the cornea (Haab). In the majority of cases a blenorrhœa of the sac is primarily produced by a stenosis of the nasal duct. This stenosis is at first merely the expression of a swelling or engorgement of the numerous veins lying beneath the mucous membrane of the ducts. As these veins are continuous with those beneath the mucous membrane of the inferior meatus and inferior turbinated bone, any congestion or catarrhal condition of the nose, in this neighborhood, will produce the same condition in the duct. Such a closure means a stagnation of accumulated tears within the sac; decomposition rapidly follows, and in a short time the contents may become highly virulent. Unless relief is offered, the mucous membrane becomes irritated, a catarrhal condition develops, and the contents, which at first were fluid and grayish in appearance, now become mixed with pus elements, and the picture of a typical blenorrhœa is established. If still neglected, the disease advances. The nature of the secretion, which at first was purulent, now changes and becomes mucous and viscid in character. Finally the mucous membrane being entirely destroyed, the secretion ceases altogether. The sac now presents a condition of atony due to a loss of elasticity in its walls, and has the appearance of a cyst filled with a clear fluid. In addition, we have the chronic blepharoconjunctivitis as a constant source of danger to the cornea. A patient suffering with blenorrhœa of the sac may at any time develop a phlegmonous dacryocystitis, or rather an acute purulent inflammation of the connective tissue surrounding the sac. This should not always be attributed to caries of the lacrymal bone, as is often done, or secondarily to ethmoidal sinusitis, which rarely, after all, occasions such a condition. That it may occur is not to be disputed. The stenosis of the nasal duct, which is primarily due to a congestion of the mucous membrane, gradually develops into a true membranous or cicatricial stricture, which is not easily overcome. In addition to the acute and chronic catarrhs of the nose, which are usually the cause of these strictures, fractures, exostoses, or even neoplasms may also obstruct this duct in such a manner as to occasion its closure. Tuberculous and syphilitic lesions in this neighborhood may occasion a similar condition.

The chief symptom produced by a blenorrhœa of the lacrymal sac is the constant overflow of tears over the lids on to the cheek. Especially annoying is this when the patient is exposed to sudden changes of temperature, or to a dusty or smoky atmosphere. Another disagreeable symptom is that the tears are apt to accumulate in the space between the lower lid and the eyeball, so that when the patient gazes downward, the cornea being bathed in this fluid, causes the rays of light to be unequally refracted, and the result is a confused optical picture. In addition, at times we notice a swelling over the lacrymal sac due to the accumulation of tears, etc. On pressure, they may be evacuated through the canaliculi on to the conjunctiva, or through the duct into the nose. In cases of acute purulent dacryocystitis we meet with all the symptoms of a violent phlegmonous inflammation, terminating, if not promptly treated, in the formation of fistulæ.

The question which I wish especially to discuss in this paper is, what is the best treatment to pursue to abate in the quickest manner possible a condition which is attended by such serious damage to the eye?

In the past years all sorts of ideas and suggestions have been offered as to the best way to eradicate this condition. I believe the following plan best adapted for the treatment of these cases:

As soon as one's suspicion is aroused that a stenosis of the lacrymal duct exists, dilate the puncta of the inferior canaliculus, with a conical-shaped sound, in order to introduce the nozzle of an Anel's syringe. Should this not be possible, simply slit up the inferior canaliculus and the introduction is now an easy matter. Inject a sterile physiological salt solution into the sac, and observe the direction which the fluid takes. If the stenosis is not very marked, almost all the fluid will pass into the nose, only a small portion appearing at the puncta above. If very much contracted, then only a small portion will appear in the nose, and the greater part in the eye. If the stricture is complete none will pass into the nose. Now examine the nose carefully and note the condition. If in doubt, cocainize the inferior meatus, to ascertain whether this closure or constriction is due to a simple engorgement, or to actual hypertrophy of the parts. If an atrophic catarrh is found, the stricture is undoubtedly of a cicatricial nature. This has been my uniform experience.

If the case is of short duration and only a partial stenosis is present, a proper treatment of the nose, together with massage and syringing of the sac, will in a short time bring about a cure. In order to determine the nature of the stricture, I employ the olive-shaped bougie of Kuhnt.[1] In order not to do any damage to the mucous membrane of the sac, it is best to slit up the inferior canaliculus, and now, according to the method of Kuhnt, at once ascertain the condition of the nasal duct. If there is a true organic stricture of not too long a duration, and the contents of the sac are not purulent, I resort to a method of relief which Passow[2] of Berlin has taught us. This consists in a removal of the anterior portion of the inferior turbinated bone, its lacrymal process, together with the inferior turbinated crest on the superior maxillary bone, thus laying bare the membranous canal of the nasal duct. The nasal duct is then slit open up to the neck of the sac. The entire operation is accomplished intranasally, under cocaine in one or two sittings. This is the extent of my conservative policy when stenosis exists. If the patient and physician possess an abundance of patience, syringing, massage, and sounds may be employed for the severer cases. Some patients may recover under such treatment, but relapses will be frequent, and the risk of a corneal infection must be borne in mind. It sometimes happens that in the newly born infant we meet with a congenital atresia of the duct, giving rise to a dacryocystoblenorrhœa. Here a slitting of the canaliculus and very careful probing, together with massage and syringing, brings about a cure.[3]

The question now arises if the above treatment is of no avail, what should be done with these patients and also in the more chronic cases?

Those who favor extirpation have established for themselves certain indications, which I think at the present day can no longer be set aside. These indications are: (1) In fistula of the lacrymal sac after long-continued suppuration (acute cases excepted). (2) In chronic blenorrhœa of the sac, with or without ectasia. (3) In chronic catarrh of the sac with an organic stricture. (4) In chronic blenorrhœa when disease of the bone with caries is present. (5) In relatively fresh cases of blenorrhœa, under the following conditions: (*a*) In ulcus serpens when the healing is very much favored by an immediate extirpation of the sac; (*b*) when an operation for cataract or glaucoma is contemplated; in fresh injuries of the cornea. (6) Tuberculosis the sac.

In regard to the best way of destroying this we should not allow ourselves to be persuaded employ either the actual cautery or chemi reagents. They mean long-continued treatme they are uncertain, and furthermore leave a which is ugly and unyielding.

The operation of removing the sac complet is to-day, in experienced hands, a simple proced In the majority of cases no general anæsthesi necessary. The entire extirpation can be d under the influence of cocaine and adrenalin, without the slightest discomfort to the patien

Platner[4] deserves the credit of having been first one to practise extirpation of the lacrymal He was followed by Berlin and Gärtner.[5] T surgeons, however, did not succeed in persua many to follow in their footsteps, due undoubt to the difficulty in their technique. The inci which they made was carried directly thro the sac. This method, experience has taught, makes the operation exceedingly tedious difficult to perform. The operation as perfor to-day differs only in slight degrees as perfor by the various surgeons. A typical operation some slight modifications from the Schreiber Axenfeld method is the following one:

Make an incision, half moon-shaped in form and one-half centimeters in length, and about half a centimeter from the inner canthus of the The incision is begun just above the internal p bral ligaments. At first it passes only through skin and subcutaneous tissue. The edges of wound are now held apart by means of a Mue speculum. This answers the purpose of a retra and assists very materially in controlling the he rhage. Should the hemorrhage be very pro then the use of the Axenfeld speculum, which h apart the upper and lower edges of the wound, be of great assistance. Now cut through the layer of muscle, then through the fibrous cap and one comes directly upon the wall of the Often it may not be possible to distinguish bet these various layers, especially in old chronic c in which adhesions have already formed, from an tension of the process through the walls of the If at all possible, and this can usually be acc plished if one is careful, do not open the sac, soiling of the wound with the contents of such a may produce an infection, and thus delay heal The sac is now carefully dissected out, with a da ing forceps and dull-pointed scissors. First inner wall is separated from the groove with the point of the scissors, then the sac is cut off al from the canaliculi and the posterior wall is detac Now, holding the sac firmly at its upper end, external wall is separated and the sac cut off c to the beginning of the nasal duct. If the sac been entirely removed, there will be left a perfe smooth cavity representing the lacrymal groo With a small curette establish a communication the nose, through the nasal duct. This serves the slight drainage of the wound, which is necess Now close the wound with three or four sutures, a found necessary. Place upon the sutured woun small roll of iodoform gauze, over this several lay of plain gauze, and then a firm pressure banda After two or three days the dressing is changed, a by the seventh day the healing is complete in typical normal case. After three weeks it is almo impossible to detect the area where the operative vasion had been made. Of course we shall meet wi cases in which it is not always possible to remove t

: *toto*, and in which it must be taken out piece-

st say, taking all things into consideration, that
st heartily endorse such a procedure. In these
the infection is not always brought about by
finger of the patient, or by the presence of a
gn body, but by a co-existing catarrh of the con-
tiva induced by a dacryocystitis.

It seems to me, therefore, if we wish to follow the rules of strict asepsis and antisepsis in the surgery of the eye, we must do in this region of the body as the surgeon has taught us to do in other portions of the body. If a source of infection exists in the body, and especially so if near a wound, take the greatest pains to destroy thoroughly that source in the quickest manner possible. Axenfeldt has proven, through the investigations of Plaut and V. Zelewski,[10] that a few weeks after extirpation of the sac a culture made from the conjunctiva is relatively free from infection.

On the continent, the number of surgeons who formerly opposed this operation is constantly growing less. I feel, therefore, although I may not have presented anything entirely new to your notice, nevertheless, if I succeed in persuading some of my conservative colleagues to treat this class of cases in a more radical way, I have accomplished the purpose of this paper.

THYMIC TRACHEOSTENOSIS, WITH REPORT OF A FATAL CASE.*

By WILLIAM WESLEY CARTER, A.M., M.D.,
NEW YORK.
ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

The term thymic tracheostenosis is used advisedly, differentiating as it does, a condition caused by pressure of an hypertrophied thymus gland upon the trachea, from an enlargement of the gland downward, and causing death by interference with the circulation. In the former case the symptoms are those of an obstruction to the passage of air in and out of the lungs and usually results in asphyxiation, while in the latter death results very suddenly from syncope. It is to the former class that the case which I report herewith belongs, and it is to this condition that I wish to call attention more especially.

My reasons for treating of this subject are two: (1) The cases are sufficiently rare to be of special interest, and should be reported; and (2) I believe that many sudden deaths among infants, attributed to some other cause, are in reality due to hypertrophy of the thymus.

The cause of simple thymic enlargement is unknown. Most of the patients are poorly nourished and rachitic, and often there is a general enlargement of the lymphatic glands—the so-called "Status Lymphaticus."

There seems to be a reciprocal relation between the thymus and the spleen, as in several cases when the thymus has been found very large the spleen has been rudimentary or absent, and *vice versa* when the thymus was congenitally absent the spleen was very large.

Microscopical examination shows merely an hyperplasia of the normal elements of the gland. When death results from syncope, it is caused by

*Read before the Society of Alumni of Bellevue Hospital.

an enlargement of the gland downward, and its pressure upon the great vessels at the base of the heart, mainly the pulmonary artery. In these cases the end is very sudden, the diagnosis probably never being made beforehand.

Sudden death among infants is not at all uncommon; the child may be found dead in its crib; it may die from so-called laryngeal stridor; it may succumb suddenly during a prolonged fit of crying; death may result during the administration of an anæsthetic, and frequently, I believe, under such circumstances, death is attributed to some innocent cause, when the *fons et origo mali* lies in the thymus gland.

After seeing my first case of hypertrophy of the thymus, I have come to realize how naturally this condition might escape the notice of even an expert diagnostician. By some it is said that death results from pressure on the pneumogastric. This, I believe, is not the case, for it seems to me that pressure upon this nerve would show some of the symptoms of interference with its normal function; that is, its inhibitory influence over the heart would be stimulated by moderate pressure, or removed entirely by very great pressure. I did not observe this in my case, nor have I been able to find such symptoms described elsewhere.

Many writers deny that an enlarged thymus can produce sufficient pressure on the trachea to cause asphyxia; but I believe that they reach this conclusion because at the autopsy the trachea has been removed in the usual way, and consequently the relations are destroyed, and any encroachment upon the lumen of the tube which may have existed has been obliterated by the elasticity of its walls when relieved from pressure. A transverse section should be made through the organs *in situ*, and the tube examined by reflected light for any modification in its coliber.

When we come to consider the following data, and remember what slight resistance the trachea of an infant offers to external pressure, there should remain in our minds no doubt upon this question. The thymus at birth weighs about half an ounce; it increases in size up to the second year, when it begins to diminish and has disappeared at puberty. It is 5 cm. long, 3½ cm. in breadth, and 8 mm. in thickness. In front it is in relation below with the manubrium sterni, and in the neck with the origins of the sternothyroid and sternohyoid muscles. Behind it lies the trachea, and below it rests upon the pericardium, being separated from the great vessels by the thoracic fascia. When naturally largest it extends into the neck frequently as far as the isthmus of the thyroid. At the point where the trachea emerges from the thorax, the vertebral column, which here bends forward, offers an unyielding point of resistance, so that the enlarging gland, supported anteriorly by the sternum, presses the trachea back and flattens it against the upper dorsal vertebræ. The distance from the manubrium sterni to the vertebral column is only 2 to 3 cm. up to the second year.

In tracheostenosis the enlargement of the gland is chiefly in an anteroposterior direction, when much depends upon the size of the upper thoracic opening, and especially its anteroposterior diameter. The positions of the head would influence pressure on the trachea at this point, for when it is thrown backward this would be increased, and *vice versa*.

The symptoms produced are those of a mechanical obstruction to the respiration. The patient is usually poorly nourished or rachitic. There is an inspiratory and expiratory stridor and cyanosis is extreme. Laryngeal stridor may be a prominent symptom. Glöcker reports three cases in which symptom was prominent, and in which the au showed that death was due to thymic enlarge

The treatment is usually unsatisfactory. however, reported a case in which he opene mediastinum, drew the gland forward and st it to the tissue over the sternum. The patie relieved at once and recovered. Spontaneo of simple, enlarged thymus occurs in six to months, and is due to increase in the size thorax and development of the rings of the t rather than to a diminution in the size of the

In reporting the following case I regre my inability to obtain permission for an a prevents my entering as fully into the det the case as I would like. The diagnosis of trophy of the thymus was made when trache was performed, and was subsequently co by exploring the local conditions through t larged tracheotomy wound after death.

M. B., female, age five weeks, was brou the Manhattan Eye and Ear Hospital on th noon of October 13.

Family history is good, mother and father Americans, are strong and healthy with no tary record of malignant, specific, or tube disease. They have two children living, t whom are strong and healthy. One child w born several years ago—its death being due t ine inertia.

The patient was very small, weighing o or six pounds, poorly nourished, and sufferi extreme dyspnœa, throwing her head ba and sidewise in her efforts to breathe—c was marked, and there was a puffiness the eyes which extended far down on the Both inspiration and expiration were atten stridor—air entered and was expelled throu nose as well as the mouth.

The child's condition dated from the ti birth, and had been steadily getting worse. had not gained any in weight, but had pro lost some, though she was breast-fed and the seemed to be suitable, as she had never ha stomach or bowel disturbance, and had neve convulsions. She could sleep about fifteen mi at a time, but only in an upright posture. could not nurse continuously; she could cry h but at such times became more cyanosed.

Physical examination of the chest showed retraction of the intercostal spaces, of th sternal and supraclavicular notches, and rec of the epigastrium at each inspiration. The stridulent noise made in the trachea obscur other auscultatory sounds.

Examination of the nasopharynx and ph revealed no cause for the condition, there present no adenoids, foreign body, or oth struction to respiration, observable by the methods of examination.

As the child's condition was urgent, an imm tracheotomy was decided upon.

During the administration of the anæ (ether) the breathing stopped several times a tificial respiration and oxygen had to be use

In performing the operation, which was atte rather low down, a mass of glandular tissu encountered, and the trachea was pushed so fa that the incision into it was made just bel cricoid cartilage. When the tube was intro at first there seemed to be some relief, but th was kept open the stridor remained, the dy was still great, and the child died from as about thirty-six hours after the tube was intro The respirations ranged from 25 to 35, and th

rom 120 to 130; the temperature a short time be-ore death rose to 106¾°. This, I believe, was due o an acute congestive pneumonia.

On enlarging the tracheotomy wound after death, removed the larynx, which I offer for your ispection; it is interesting merely as the normal rgan of a child five weeks old, and as demonstrating ie fact that no obstruction to the respiration isted at this point. Investigating further, I dis-vered that an enormously hypertrophied thymus and filled the upper thoracic opening, pressing the achea back against the vertebral column, and ttending upward in the neck as high as the larynx.

A study of this case leads me to make the fol-wing observations and suggestions:

1. In all cases of laryngeal stridor it should be termined whether or not the thymus is enlarged.

2. On account of surgical shock being badly rne by infants, and especially those in this con-tion, if the symptoms are *not* urgent, postural eatment should be tried, and if, in any position the head and neck, relief is afforded, that position ould be maintained by suitable apparatus until ture has effected a cure by enlargement of the orax, strengthening the tracheal rings, and diminu-n in the size of the gland.

3. Intubation, tracheotomy, ahd artificial respi-tion do no good.

4. The surgical procedure of opening the medi-num, bringing forward the gland and stitching to the tissue over the sternum, should be per-med immediately if there is danger from asphyxia.
